

Volatility-Managed Portfolios

ALAN MOREIRA and TYLER MUIR*

ABSTRACT

Managed portfolios that take less risk when volatility is high produce large alphas, increase Sharpe ratios, and produce large utility gains for mean-variance investors. We document this for the market, value, momentum, profitability, return on equity, investment, and betting-against-beta factors, as well as the currency carry trade. Volatility timing increases Sharpe ratios because changes in volatility are not offset by proportional changes in expected returns. Our strategy is contrary to conventional wisdom because it takes relatively less risk in recessions. This rules out typical risk-based explanations and is a challenge to structural models of time-varying expected returns.

We especially thank Nick Barberis for many useful discussions. We also thank Ken French, Lasse Pedersen, Alexi Savov, Adrien Verdelhan, and Lu Zhang for providing data. Both authors disclose that, after our work had already circulated, this research was solicited for compensated presentations at Arrowstreet Capital, Mellon Capital, Panagora Asset Management, and Phase Capital.

We construct portfolios that scale monthly returns by the inverse of their previous month's realized variance, decreasing risk exposure when variance was recently high and vice versa. We call these volatility-managed portfolios. We document that this simple trading strategy earns large alphas across a wide range of asset pricing factors, suggesting that investors can benefit from volatility timing. We then interpret these results from both a portfolio choice and a general equilibrium perspective.

We motivate our analysis from the vantage point of a mean-variance investor, who adjusts their allocation according to the attractiveness of the mean-variance trade-off, μ_t / σ_t^2 . Because variance is highly forecastable at short horizons, and variance forecasts are only weakly related to future returns at these horizons, our volatility-managed portfolios produce significant risk-adjusted returns for the market, value, momentum, profitability, return on equity, investment, and betting-against-beta factors in equities as well as for the currency carry trade. Annualized alphas and Sharpe ratios with respect to the original factors are substantial. For the market portfolio our strategy produces an alpha of 4.9%, an appraisal ratio of 0.33, and an overall 25% increase in the buy-and-hold Sharpe ratio.

Figure 1 provides intuition for our results for the market portfolio. In line with our trading strategy, we group months by the previous month's realized volatility and plot average returns, volatility, and the mean-variance trade-off over the subsequent month. There is little relation between lagged volatility and average returns but there is a strong relationship between lagged volatility and current volatility. This means that the mean-variance trade-off weakens in periods of high volatility. From a portfolio choice perspective, this pattern implies that a standard mean-variance investor should time volatility,

that is, take more risk when the mean-variance trade-off is attractive (volatility is low), and take less risk when the mean-variance trade-off is unattractive (volatility is high). From a general equilibrium perspective, this pattern presents a challenge to representative agent models focused on the dynamics of risk premia. From the vantage point of these theories, the empirical pattern in Figure 1 implies that an investor's willingness to take stock market risk must be higher in periods of high stock market volatility, which runs counter to most theories. Sharpening the puzzle is the fact that volatility is typically high during recessions, financial crises, and in the aftermath of market crashes when theory generally suggests investors should, if anything, be more risk averse relative to normal times.

[Figure 1 about here]

Our volatility-managed portfolios reduce risk-taking during these bad times – times when the conventional wisdom is to increase risk-taking or hold risk-taking constant.¹ For example, in the aftermath of the sharp price declines in the fall of 2008, a widely held view was that those that reduced positions in equities were missing a once-in-a-generation buying opportunity.² Yet our strategy cashed out almost completely and returned to the market only as the spike in volatility receded. Indeed, we show that our

¹For example, in August 2015, a period of high volatility, Vanguard – a leading mutual fund company – gave advice consistent with this view :“What to do during market volatility? Perhaps nothing.” See <https://personal.vanguard.com/us/insights/article/market-volatility-082015>.

²See, for example, John Cochrane (“Is now time to buy stocks?” 2008, Wall Street Journal) and Warren Buffet (“Buy America. I am”, 2008, The New York Times) make the case for this view. However, consistent with our main findings, Nagel et al. (2016) show that many households respond to volatility by selling stocks in 2008 and that this effect is larger for higher income households, which may be more sophisticated traders.

simple strategy worked well throughout several crisis episodes, including the Great Depression, the Great Recession, and 1987 stock market crash. More broadly, we show that our volatility-managed portfolios take substantially less risk during recessions.

These facts may be surprising in light of evidence showing that expected returns are high in recessions (Fama and French (1989)) and in the aftermath of market crashes (Muir (2016)). To better understand the business cycle behavior of the risk-return trade-off, we combine information about time-variation in both expected returns and variance. Using a vector autoregression (VAR) we show that in response to a variance shock, the conditional variance initially increases by far more than the expected return. A mean-variance investor would decrease his or her risk exposure by around 50% after a one-standard-deviation shock to the market variance. However, since volatility movements are less persistent than movements in expected returns, our optimal portfolio strategy prescribes a gradual increase in exposure as the initial volatility shock fades. This difference in persistence helps reconcile the evidence on countercyclical expected returns with the profitability of our strategy. Relatedly, we also show that our alphas slowly decline as the rebalancing period grows because current volatility is a weaker forecast for future volatility as we increase horizon.

We conduct an extensive battery of tests to evaluate the robustness of our result. We show that the typical investor can benefit from volatility timing even if subject to realistic transaction costs and tight leverage constraints. The strategy works just as well if implemented through options to achieve high embedded leverage, which further suggests that leverage constraints are unlikely to explain the high alphas of our volatility-managed

strategies. Consistent with these results, we show that our volatility-managed strategy is different from strategies that explore low-risk anomalies in the cross-section such as risk parity (Asness, Frazzini, and Pedersen (2012)) and betting against beta (Frazzini and Pedersen (2014)). Moreover, we also study a volatility-managed version of the betting-against-beta factor to show how our approach can also be combined with a cross-sectional low-risk strategy.

In the Internet Appendix we show that our strategy works for a credit-risk factor formed from excess corporate bond returns, that it works for international stock market indices, that it can be further improved through the use of more sophisticated models of variance forecasting, that it does not generate fatter left tails than the original factors or create option-like payoffs, that it is less exposed to volatility shocks than the original factors (ruling out explanations based on the variance risk premium), that it cannot be explained by downside market risk (Ang, Chen, and Xing (2006), Lettau, Maggiori, and Weber (2014)), disaster risk, or jump risk, and that it outperforms not only using alpha and Sharpe ratios but also manipulation-proof measures of performance (Goetzmann et al. (2007)).³

Once we establish that the profitability of our volatility-managed portfolios is a robust feature of the data, we study the economic interpretation of our results in terms of utility gains, the behavior of the aggregate price of risk, and equilibrium models. First, we find that mean-variance utility gains from our volatility-managed strategy are large, about 65% of lifetime utility. This compares favorably with Campbell and Thompson (2008),

³The Internet Appendix is available in the online version of the article on the Journal of Finance website.

and a longer literature on return predictability, who find mean-variance utility benefits of 35% from timing expected returns.

Next we show more formally how the alpha of our volatility-managed portfolio relates to the risk-return trade-off. In particular, we show that $\alpha \propto -cov(\mu_t/\sigma_t^2, \sigma_t^2)$. Thus, consistent with Figure 1, the negative relationship between μ_t/σ_t^2 and conditional variance drives our positive alphas. The positive alphas we document across all strategies implies that the factor prices of risk, μ_t/σ_t^2 , are negatively related to factor variances in each case. When the factors span the conditional mean-variance frontier, this result tells us about the aggregate variation in the price of risk, that is, about compensation for risk over time and the dynamics of the stochastic discount factor. Formally, we show how to use our strategy alpha to construct a stochastic discount factor that incorporates these dynamics and that can unconditionally price a broader set of dynamic strategies with a large reduction in pricing errors.

Lastly, we contrast the price of risk dynamics we recover from the data with leading structural asset pricing theories. These models all feature a weakly positive correlation between μ_t/σ_t^2 and variance so that volatility-managed alphas are either negative or near zero. This is because in bad times when volatility increases, effective risk-aversion in these models also increases, driving up the compensation for risk. This is a typical feature of standard rational, behavioral, and intermediary models of asset pricing. More specifically, the alphas of our volatility-managed portfolios pose a challenge to macro-finance models that is statistically sharper than standard risk-return regressions, which produce mixed and statistically weak results (see Glosten, Jagannathan, and Run-

kle (1993), Whitelaw (1994), Lundblad (2007), Lettau and Ludvigson (2003)).⁴ Consistent with this view, we simulate artificial data from these models and show that they are able to produce risk-return trade-off regressions that are not easily rejected by the data. However, they are very rarely able to produce return histories consistent with the volatility-managed portfolio alphas that we document. Thus, the facts documented here are sharper challenges to standard models in terms of the dynamic behavior of volatility and expected returns.

The general equilibrium results and broader economic implications that we highlight also demonstrate why our approach differs from other asset allocation papers that use volatility, because our results can speak to the evolution of the aggregate risk-return trade-off. For example, Fleming, Kirby, and Ostdiek (2001, 2003) study daily asset allocation across stocks, bonds, and gold based on estimating the conditional covariance matrix that performs cross-sectional asset allocation, and Barroso and Santa-Clara (2015) and Daniel and Moskowitz (2016) study volatility timing related to momentum crashes.⁵ Instead, our approach focuses on the time series of many aggregate priced factors, which allows us to give economic content to the returns on the volatility-managed strategies.

This paper proceeds as follows. Section I documents our main empirical results. Section II studies our strategy in more detail and provides various robustness checks. Section III shows formally the economic content of our volatility-managed alphas. Section IV discusses implications for structural asset pricing models. Section V concludes.

⁵Daniel et al. (2015) also look at a strategy related to ours for currencies.

I. Main Results

A. Data Description

We use both daily and monthly factors from Kenneth French’s website on Mkt, SMB, HML, Mom, RMW, and CMA. The first three factors are the original Fama-French three factors (Fama and French (1996)), while the last two are a profitability and an investment factor that they use in their five-factor model (Fama and French (2015), Novy-Marx (2013)). Mom represents the momentum factor, which goes long past winners and short past losers. We include daily and monthly data from Hou et al. (2014), which includes an investment factor, IA, and a return on equity factor, ROE. In addition, we include the betting-against-beta (BAB) factor from Frazzini and Pedersen (2014). Finally, we use data on currency returns from Lustig, Roussanov, and Verdelhan (2011) provided by Adrien Verdelhan. We use the monthly high minus low carry factor formed on the interest rate differential, or forward discount, of various currencies. We have monthly data on returns and use daily data on exchange rate changes for the high and low portfolios to construct our volatility measure. We refer to this factor as “Carry” or “FX” to save on notation and to emphasize that it is a carry factor formed in foreign exchange markets.

B. Portfolio Formation

We construct our volatility-managed portfolios by scaling an excess return by the inverse of its conditional variance. Each month our strategy increases or decreases risk exposure to the portfolio according to variation in our measure of conditional variance.

The managed portfolio is then

$$f_{t+1}^\sigma = \frac{c}{\hat{\sigma}_t^2(f)} f_{t+1}, \quad (1)$$

where f_{t+1} is the buy-and-hold portfolio excess return, $\hat{\sigma}_t^2(f)$ is a proxy for the portfolio's conditional variance, and the constant c controls the average exposure of the strategy. For ease of interpretation, we choose c so that the managed portfolio has the same unconditional standard deviation as the buy-and-hold portfolio.⁶

The motivation for this strategy comes from the portfolio problem of a mean-variance investor who is deciding how much to invest in a risky portfolio (e.g., the market portfolio). The optimal portfolio weight is proportional to the attractiveness of the risk-return trade-off, that is, $w_t^* \propto \frac{E_t[f_{t+1}]}{\hat{\sigma}_t^2(f)}$.⁷ Motivated by empirical evidence that volatility is highly variable, persistent, and does not predict returns, we approximate the conditional risk-return trade-off by the inverse of the conditional variance. In our main results, we keep the portfolio construction even simpler by using the previous month's realized variance as a proxy for the conditional variance,

$$\hat{\sigma}_t^2(f) = RV_t^2(f) = \sum_{d=1/22}^1 \left(f_{t+d} - \frac{\sum_{d=1/22}^1 f_{t+d}}{22} \right)^2. \quad (2)$$

An appealing feature of this approach is that it can be easily implemented by an in-

⁶Importantly, c has no effect on our strategy's Sharpe ratio, and thus the fact that we use the full sample to compute c does not impact our results.

⁷This is true in the univariate case but also in the multifactor case when factors are approximately uncorrelated.

vestor in real time and does not rely on any parameter estimation. We plot the realized volatility for each factor in Figure 2. In the Internet Appendix, we consider the use of more sophisticated variance forecasting models.⁸

[Figure 2 about here]

C. *Empirical Methodology*

We run a time-series regression of the volatility-managed portfolio on the original factors,

$$f_{t+1}^{\sigma} = \alpha + \beta f_{t+1} + \epsilon_{t+1}. \quad (3)$$

A positive intercept implies that volatility timing increases Sharpe ratios relative to the original factors. When this test is applied to systematic factors (e.g., the market portfolio) that summarize pricing information for a wide cross-section of assets and strategies, a positive alpha implies that our volatility-managed strategy expands the mean-variance frontier. We rely on the extensive empirical asset pricing literature in identifying these factors. In particular, a large empirical literature finds that the factors we use summarize the pricing information contained in a wide set of assets and hence we can focus on understanding the behavior of just these factors.

⁸See also Ang (2014) for an example of volatility timing using the VIX for a shorter sample.

D. Single-Factor Portfolios

We first apply our analysis factor by factor. The single-factor alphas have economic interpretation when the individual factors accurately describe the opportunity set of investors or these factors have low correlation with each other, that is, each factor captures a different dimension of risk. The single-factor results are also useful to show that the empirical pattern we document is pervasive across factors and that our results are uniquely driven by the time-series relationship between risk and return.

Table I reports results from running a regression of the volatility-managed portfolios on the original factors. We see positive, statistically significant intercepts (α 's) in most cases. The managed market portfolio on its own deserves special attention because this strategy would have been easily available to the average investor in real time; moreover the results in this case directly relate to a long literature on market timing that we discuss below.⁹ The scaled market factor has an annualized alpha of 4.86% and a beta of only 0.6. While most alphas are strongly positive, the largest is for the momentum factor.¹⁰ Finally, in the bottom of the table, we show that these results are relatively unchanged when we control for the Fama-French three factors in addition to the original factor in every regression. Below we discuss multifactor adjustments more broadly.

[Table I about here]

The top panel of Figure 3 plots the cumulative nominal returns to the volatility-

⁹The typical investor will likely find it difficult to trade the momentum factor, for example.

¹⁰This is consistent with Barroso and Santa-Clara (2015), who find that strategies that avoid large momentum crashes by timing momentum volatility perform exceptionally well.

managed market factor compared to a buy-and-hold strategy from 1926 to 2015. We invest \$1 in 1926 and plot the cumulative returns to each strategy on a log scale. The volatility-managed factor realizes relatively steady gains, which cumulate to around \$20,000 at the end of the sample versus about \$4,000 for the buy-and-hold strategy. The lower panels of Figure 3 plot the drawdown and annual returns of the strategy relative to the market, which helps us understand when our strategy loses money relative to the buy-and-hold strategy. Our strategy takes relatively more risk when volatility is low (e.g., the 1960s) and thus, not surprisingly, its largest losses are concentrated in these times. In contrast, large market losses tend to happen when volatility is high (e.g., the Great Depression or recent financial crisis), and our strategy avoids these episodes. As a result, the worst time periods for our strategy do not overlap much with the worst market crashes. This result illustrates that our strategy works by shifting when it takes market risk and not by loading on extreme market realizations as profitable option strategies typically do.

[Figure 3 about here]

In all tables reporting α 's, we also include the root mean squared error, which allows us to construct the managed factor excess Sharpe ratio (or “appraisal ratio”) given by $\frac{\alpha}{\sigma_\epsilon}$, thus giving us a measure of the extent to which dynamic trading expands the slope of the mean-variance efficient frontier spanned by the original factors. More specifically, the new Sharpe ratio is $SR_{new} = \sqrt{SR_{old}^2 + \left(\frac{\alpha}{\sigma_\epsilon}\right)^2}$, where SR_{old} is the Sharpe ratio given by the original non-scaled factor. For example, in Table I, scaled momentum has an α of 12.5 and a root mean square error of around 50, which means that its annualized appraisal

ratio is $\sqrt{12} \frac{12.5}{50} = 0.875$. The scaled markets' annualized appraisal ratio is 0.34.¹¹ Other notable appraisal ratios across factors are: HML (0.20), profitability (0.41), carry (0.44), ROE (0.80), investment (0.32), and BAB (0.66).

An alternative way to quantify the economic relevance of our results is from the perspective of a simple mean-variance investor. The percentage utility gain is

$$\Delta U_{MV}(\%) = \frac{SR_{new}^2 - SR_{old}^2}{SR_{old}^2}. \quad (4)$$

Our results imply large utility gains. For example, a mean-variance investor who can only trade the market portfolio can increase lifetime utility by 65% through volatility timing. We extend these computations to long-lived investors and more general preferences in Moreira and Muir (2016). The extensive market timing literature provides a useful benchmark for these magnitudes. Campbell and Thompson (2008) estimate that the utility gain of timing expected returns is 35% of lifetime utility. Volatility timing not only generates gains almost twice as large, but also works across multiple factors.

E. Multifactor Portfolios

We now extend our analysis to a multifactor environment. We first construct a portfolio by combining the multiple factors. We choose weights so that our multifactor portfolio is mean-variance efficient for the set of factors, and as such, the multifactor portfolio prices not only the individual factors but also the wide set of assets and strategies priced

¹¹We need to multiply the monthly appraisal ratio by $\sqrt{12}$ to arrive at annual numbers. We multiplied all factor returns by 12 to annualize them but that also multiplies volatilities by 12, so the Sharpe ratio will still be a monthly number.

by them. We refer to this portfolio as multifactor mean-variance efficient (MVE). It follows that the MVE alpha is the right measure of expansion in the mean-variance frontier. Specifically, a positive MVE alpha implies that our volatility-managed strategy increases Sharpe ratios relative to the best buy-and-hold Sharpe ratio achieved by someone with access to the multiple factors.

We construct the MVE portfolio as follows. Let F_{t+1} be a vector of factor returns and b the static weights that produce the maximum in-sample Sharpe ratio. We define the MVE portfolio as $f_{t+1}^{MVE} = b' F_{t+1}$. We then construct

$$f_{t+1}^{MVE,\sigma} = \frac{c}{\hat{\sigma}_t^2(f_{t+1}^{MVE})} f_{t+1}^{MVE}, \quad (5)$$

where again c is a constant that normalizes the variance of the volatility-managed portfolio such that it is equal to the MVE portfolio. Thus, our volatility-managed portfolio shifts the conditional beta on the MVE portfolio, but *does not* change the relative weights across the individual factors. As a result, our strategy focuses uniquely on the time-series aspect of volatility timing.

In Table II, we show that the volatility-timed MVE portfolios have positive alpha with respect to the original MVE portfolios for all combinations of factors we consider including the Fama-French (1996, 2015) three and five factors or the Hou, Xue, and Zhang (2014) factors. This finding is robust to including the momentum factor as well. Appraisal ratios are all economically large and range from 0.33 to 0.91. Note that the original MVE Sharpe ratios are likely to be overstated relative to the truth, since the weights are constructed in-

sample. Thus, the increase in Sharpe ratios we document are likely to be understated.¹²

[Table II about here]

We also analyze these MVE portfolios across three 30-year subsamples (1926 to 1955, 1956 to 1985, and 1986 to 2015) in Panel B. The results generally show the earlier and later periods as having stronger, more significant alphas, with the results being weaker in the 1956 to 1985 period, though we note that point estimates are positive for all portfolios and all three subsamples. This should not be surprising as our results rely on a large degree of variation in volatility to work. For example, if volatility were constant over a particular period, our strategy would be identical to the buy-and-hold strategy and alphas would be zero. Volatility varied far less in the 1956 to 1986 period, consistent with lower alphas during this time. In the Internet Appendix we further document these results over rolling subsamples.

II. Understanding the Profitability of Volatility Timing

In this section we investigate our strategy from several different perspectives. Each section is self-contained so a reader can easily skip across sections without loss.

A. *Business Cycle Risk*

In Figure 3, we can see that the volatility-managed factor has a lower standard deviation through recession episodes like the Great Recession where volatility was high. Table

¹²We thank Tuomo Vuolteenaho for raising this point.

III makes this point more clearly across our factors. Specifically, we run regressions of each of our volatility-managed factors on the original factors but also add an interaction term that includes an NBER recession dummy. The coefficient on this term represents the conditional beta of our strategy on the original factor during recession periods relative to nonrecession periods. The results in the table show that, across the board for all factors, our strategies take less risk during recessions and thus have lower betas during recessions. For example, the nonrecession market beta of the volatility-managed market factor is 0.83 but the recession beta coefficient is -0.51, making the beta of our volatility-managed portfolio conditional on a recession equal to 0.32. Finally, by looking at Figure 2, which plots the time-series realized volatility of each factor, we can clearly see that volatility for all factors tends to rise in recessions. Thus, our strategies decrease risk exposure in NBER recessions. This makes it difficult for a business cycle risk story to explain our facts. However, we still review several specific risk-based stories below.

[Table III about here]

B. Transaction Costs

We show that our strategies survive transaction costs. These results are given in Table IV. Specifically, we evaluate our volatility timing strategy for the market portfolio when including empirically realistic transaction costs. We consider various strategies that capture volatility timing but reduce trading activity, including using standard deviation instead of variance, using expected rather than realized variance, and two strategies that

cap the strategy's leverage at 1 and 1.5, respectively. Each of these reduces trading and hence transaction costs. We report the average absolute change in monthly weights, expected return, and alpha of each strategy before transaction costs. We then report the alpha when including various transaction cost assumptions. The 1bp cost comes from Fleming, Kirby, and Ostdiek (2003), the 10bps comes from Frazzini, Israel, and Moskowitz (2015), who assume the investor is trading about 1% of daily volume, and the next column adds an additional 4bps to account for transaction costs increasing in high volatility episodes. Specifically, we use the slope coefficient in a regression of transaction costs on VIX from Frazzini, Israel, and Moskowitz (2015) to evaluate the impact of a move in VIX from 20% to 40%, which represents the 98th percentile of VIX. Finally, the last column backs out the implied trading costs in basis points needed to drive our alphas to zero in each of the cases. The results in Table IV indicate that the strategy survives transactions costs, even in high volatility episodes where such costs likely rise (indeed, we take the extreme case in which VIX is at its 98th percentile). Alternative strategies that reduce trading costs are much less sensitive to these costs.

[Table IV about here]

Overall, we show that the annualized alpha of the volatility-managed strategy decreases somewhat for the market portfolio, but is still very large. We do not report results for all factors, since we do not have good measures of transaction costs for implementing the original factors, much less their volatility-managed portfolios.

C. *Leverage Constraints*

In this section we explore the importance of leverage for our volatility-managed strategy. We show that the typical investor can benefit from our strategy even under a tight leverage constraint.

Panel A of Table V documents the upper distribution of the weights in our baseline strategy for the volatility-managed market portfolio. The median weight is near 1. The 75th, 90th, and 99th percentiles are 1.6, 2.6, and 6.4. Our baseline strategy thus uses modest leverage most of the time but does imply rather substantial leverage in the upper part of the distribution, when realized variance is low.

[Table V about here]

We explore several alternative implementations of our strategy. The first uses realized volatility instead of realized variance. This makes the weights far less extreme, with the 99th percentile around 3 instead of 6. Second, using expected variance from a simple AR(1) rather than realized variance also reduces the extremity of the weights. Both of these alternatives keep roughly the same Sharpe ratio as the original strategy. Last, we consider our original strategy but cap the weights to be below 1 or 1.5, which captures a tight no-leverage constraint and leverage of 50%, which is consistent with a standard margin requirement. The Sharpe ratios do not change but of course the leverage-constrained portfolios have lower alphas because risk weights are, on average, lower. Alphas of all of these strategies are still statistically significant.

Because Sharpe ratios are not a good metric to assess utility gains in the presence of

leverage constraints, in Figure 4 we compute the utility gains for a mean-variance investor. Specifically, consider a mean-variance investor who follows a buy-and-hold strategy for the market with risk exposure $w = \frac{1}{\gamma} \frac{\mu}{\sigma^2}$ and an investor who times volatility by setting $w_t = \frac{1}{\gamma} \frac{\mu}{\sigma_t^2}$. For any risk-aversion, γ , we can compute the weights and evaluate utility gains. Figure 4 shows a gain of around 60% for the market portfolio from volatility timing for an unconstrained investor.¹³ With no leverage limit, percentage utility gains are the same regardless of risk-aversion because investors can freely adjust their average risk exposure.

[Figure 4 about here]

Next, we impose a constraint on leverage, so that both the static buy-and-hold weight w and the volatility timing weight w_t must be less than or equal to 1 (no leverage) or 1.5 (standard margin constraint). We then evaluate utility benefits. For investors with high risk-aversion this constraint is essentially never binding and their utility gains are unaffected. As we decrease investors' risk-aversion, however, we increase their target risk exposure and are more likely to hit the constraint. Taken to the extreme, an investor who is risk neutral will desire infinite risk exposure, and hence will do zero volatility timing, because w_t will always be above the constraint. To get a sense of magnitudes, Figure 4 shows that an investor whose target risk exposure is 100% in stocks (risk-aversion $\gamma \approx 2.2$) and who faces a standard 50% margin constraint will see a utility benefit of about

¹³Note that 60% is slightly different from the 65% that we obtain in the Sharpe ratio-based calculation in Section I.D. The small difference is due to the fact that here we assume that the mean-variance investor only invests in the volatility-managed portfolio, while in Section I.D the investor is investing in the optimal MVE portfolio combination.

45%. An investor who targets a 60/40 portfolio of stocks and T-bills and faces a tight no-leverage constraint will have a utility benefit of about 50%. Therefore, the results suggest fairly large benefits to volatility timing even with tight leverage constraints.

For investors whose risk-aversion is low enough, our baseline strategy requires some way to achieve a large risk exposure when volatility is very low. To address the concern that very high leverage might be costly or unfeasible, we implement our strategy using options in the S&P 500, which provide embedded leverage. Of course, there may be many other ways to achieve a β above 1 – options simply provide one example. We use the option portfolios from Constantinides, Jackwerth, and Savov (2013), focusing on in-the-money call options with maturities of 60 and 90 days and whose market beta is around 7. Whenever the strategy prescribes leverage, we use the option portfolios to achieve our desired risk exposure. In Panel B of Table V, we compare the strategy implemented with options to the strategy implemented with leverage. The alphas are very similar, which suggests that our results are not due to leverage constraints, even for investors with relatively low risk-aversion.¹⁴

Black (1972), Black, Jensen, and Scholes (1972), and Frazzini and Pedersen (2014) show that leverage constraints can distort the risk-return trade-off in the cross-section. The idea is that the embedded leverage of high-beta assets make them attractive to investors that are leverage-constrained. One could argue that low-volatility periods are analogous to

¹⁴In light of recent work by Frazzini and Pedersen (2012), the fact that our strategy can be implemented using options should not be surprising. Frazzini and Pedersen (2012) show that, for option strategies on the S&P 500 index with embedded leverage up to 10, there is no difference in average returns relative to strategies that leverage the cash index. This implies that our strategy can be easily implemented using options for relatively high levels of leverage.

low-beta assets, and as such have expected returns that are too high relative to investors willingness to take risk. While in theory leverage constraints could explain our findings, we find that most investors can benefit from volatility timing under very tight leverage constraints. Therefore constraints do not seem a likely explanation for our findings.

These results on leverage constraints and the results on transaction costs together suggest that our strategy can be realistically implemented in real time.

D. Contrasting with Cross-Sectional Low-Risk Anomalies

In this section we show empirically that our strategy is also very different from strategies that explore a weak risk-return trade-off in the *cross-section* of stocks, which are often attributed to leverage constraints.

The first strategy, popular among practitioners, is risk parity, which mostly relates to cross-sectional allocation. Specifically, risk parity ignores information about expected returns and co-variances and allocates to asset classes or factors in a way that makes the total volatility contribution of each asset the same. We follow Asness, Frazzini, and Pedersen (2012) and construct risk parity factors according to $RP_{t+1} = b'_t f_{t+1}$, where $b_{i,t} = \frac{1/\tilde{\sigma}_t^i}{\sum_i 1/\tilde{\sigma}_t^i}$ and $\tilde{\sigma}_t^i$ is a rolling three-year estimate of volatility for each factor (again exactly as in Asness, Frazzini, and Pedersen (2012)). This implies that if the volatility of one factor increases relative to other factors, the strategy will rebalance from the high-volatility factor to the low-volatility factor. In contrast, when we time combinations of factors, as in Table II, we keep the relative weights of all factors constant and only increase or decrease overall risk exposure based on total volatility. Thus, our volatility timing is

conceptually quite different from risk parity. To assess this difference empirically, in Table VI we include a risk parity factor as an additional control in our time-series regression. The alphas are basically unchanged. We thus find that controlling for the risk parity portfolios constructed following Asness, Frazzini, and Pedersen (2012) has no effect on our results, which suggests that we are picking up a different empirical phenomenon.

[Table VI about here]

The second strategy is the betting-against-beta (BAB) factor of Frazzini and Pedersen (2014). They show that a strategy that goes long low-beta stocks and shorts high-beta stocks can earn large alphas relative to the CAPM and the Fama-French three-factor model that includes a momentum factor. Conceptually, our strategy is quite different. While the high risk-adjusted return of the BAB factor reflects the fact that differences in average returns are not explained by differences in CAPM betas in the cross-section, our strategy is based on the fact that across time periods, differences in average returns are not explained by differences in stock market variance. Our strategy is capturing different phenomena in the data. In the last column of Table VI we show further that a volatility-managed version of the BAB portfolio also earns large alphas relative to the buy-and-hold BAB portfolio. Therefore, one can volatility time the cross-sectional anomaly. In addition, we find that our alphas are not impacted if we add the BAB factor as a control (see the Internet Appendix). Thus, our *time-series* volatility-managed portfolios are distinct from the low-beta anomaly documented in the cross-section.

E. Volatility Co-Movement

A natural question is whether one can implement our results using a common volatility factor. Because realized volatility is highly correlated across factors, normalizing by a common volatility factor does not drastically change our results. To see this, we compute the first principal component of realized variance across all factors and normalize each factor by $\frac{1}{RV_t^{PC}}$.¹⁵ This is in contrast to normalizing by each factor's own realized variance. Table VII reports the results, which are slightly weaker than the main results. For most factors the common volatility timing works about the same. However, it is worth noting that the alpha for the currency carry trade disappears. The realized volatility of the carry trade returns is quite different from the other factors (likely because it represents an entirely different asset class), and hence it is not surprising that timing this factor with a common volatility factor from (mostly) equity portfolios will work poorly.

[Table VII about here]

The strong co-movement among equities validates our approach in Section I.E, where we impose a constant weight across portfolios to construct the MVE portfolio.

F. Horizon Effects

We have implemented our strategy by rebalancing it once a month and running time-series regressions at the monthly frequency. A natural question to ask is whether our results hold at lower frequencies. Less frequent rebalancing periods might be interesting

¹⁵Using an equal-weighted average of realized volatilities, or even just the realized volatility of the market return, produces similar results.

from the perspective of macro-finance models, which are often used to explain variation in risk premia and the price of risk at quarterly or annual frequencies. Lower frequencies are also useful to better understand the full dynamic relationship between volatility shocks, expected returns, and the price of risk. In particular, they allow us to reconcile our results with the well-known empirical facts that movements in both stock-market variance and expected returns are countercyclical (French et al. (1987), Lustig and Verdelhan (2012)).

We start by studying the dynamics of risk and return through a vector autoregression (VAR) because it is a convenient tool to document how volatility and expected returns respond dynamically to a volatility shock over time. We run a VAR at the monthly frequency with one lag of (log) realized variance, realized returns, and the price to earning ratio (CAPE from Robert Shiller's website) and plot the impulse response function to trace out the effects of a variance shock. We choose the ordering of the variables so that the variance shock can contemporaneously affect realized returns and CAPE.

Figure 5 plots the response to a one-standard-deviation expected variance shock. While expected variance spikes on impact, this shock dies out fairly quickly, consistent with variance being strongly mean-reverting. Expected returns, however, rise much less on impact but stay elevated for a longer period of time. Given the increase in variance but only small and persistent increase in expected return, the lower panel shows that it is optimal for the investor to reduce his portfolio exposure by 50% on impact because of an unfavorable risk-return trade-off. The portfolio share is consistently below 1 for roughly 12 months after the shock.

[Figure 5 about here]

The lower persistence of volatility shocks implies that the risk-return trade-off initially deteriorates but gradually improves as volatility declines through a recession. Thus, our results are not in conflict with the evidence that risk premia are countercyclical. Instead, after a large market crash such as that in October 2008, our strategy initially gets out of the market to avoid an unfavorable risk-return trade-off, but captures much of the persistent increase in expected returns by buying back in when the volatility shock subsides.

However, the estimated response of expected returns to a volatility shock should be read with caution, as return predictability regressions are poorly estimated. With this in mind, we also study the behavior of our strategy at lower frequencies. Specifically, we form portfolios as before, using weights proportional to monthly realized variance, but now we hold the position for T months before rebalancing. We then run our time-series alpha test at the same frequency. Letting $f_{t \rightarrow t+T}$ be the cumulative factor excess returns from buying at the end of month T and holding until the end of month $t + T$, we run,

$$\frac{c}{\hat{\sigma}_t^2(f_{t+1})} f_{t \rightarrow t+T} = \alpha + \beta f_{t \rightarrow t+T} + \epsilon_{t+T} \quad (6)$$

with non-overlapping data. Results are in Figure 6. We show alphas and appraisal ratios for the market and the MVE portfolios based on the Fama-French three factors and momentum factor. Alphas are statistically significant for longer holding periods but gradually decline in magnitude. For example, for the market portfolio, alphas are statistically

different from zero (at the 10% confidence level) for up to 18 months. This same pattern holds for the two MVE portfolios we consider.

[Figure 6 about here]

These results are broadly consistent with the VAR in that alphas decrease with horizon. However, empirically, volatility seems to be more persistent at moderate or long horizons than implied by its very short-term dynamics. For example, the estimated VAR dynamics implies that volatility has a near-zero 12-month autocorrelation, while the non-parametric estimate is larger than 0.2. This means the alphas decline more slowly than the VAR suggests.

The economic content of the long-horizon alphas is similar to the monthly results. These results imply that even at lower frequencies, there is a negative relation between variance and the price of risk (see Section III).

G. Additional Analysis

We conduct a number of additional robustness checks of our main result but leave the details to the Internet Appendix. We show that our strategy works for a credit-risk factor formed from excess corporate bond returns, that it works for international stock market indices, that it can be further improved through the use of more sophisticated models of variance forecasting, that it does not generate fatter left tails than the original factors or create option-like payoffs, and that it outperforms not only using alpha and Sharpe ratios but also manipulation-proof measures of performance (Goetzmann, Ingersoll, Spiegel,

and Welch (2007)). We also find that our volatility-managed factors are less exposed to volatility shocks than the original factors (ruling out explanations based on the variance risk premium), and cannot be explained by downside market risk (Ang, Chen, and Xing (2006), Lettau, Maggiori, and Weber (2014)), disaster risk, or jump risk.

III. Theoretical Framework

In this section we provide a theoretical framework to interpret our findings. We start by making the intuitive point that our alphas are proportional to the co-variance between variance and the factor price of risk. We then impose more structure to derive aggregate pricing implications.

We get cleaner formulas in continuous time. Consider a portfolio total value process R_t with expected excess return μ_t and conditional volatility σ_t (i.e. $dR_t = (r_t + \mu_t)dt + \sigma_t dB_t$, where r_t is the instantaneous risk-free rate). Construct the volatility-managed version of this return exactly as in equation (1), that is, $dR_t^\sigma = r_t dt + \frac{c}{\sigma_t^2}(dR_t - r_t dt)$, where c is a normalization constant. The α of a time-series regression of the volatility-managed portfolio excess return $dR_t^\sigma - r_t dt$ on the original portfolio excess return $dR_t - r_t dt$ is given by

$$\alpha = E[dR_t^\sigma - r_t dt]/dt - \beta E[dR_t - r_t dt]/dt. \quad (7)$$

Using the fact that $E[dR_t^\sigma - r_t dt]/dt = cE\left[\frac{\mu_t}{\sigma_t^2}\right]$, $\beta = \frac{c}{E[\sigma_t^2]}$, and $cov\left(\frac{\mu_t}{\sigma_t^2}, \sigma_t^2\right) = E[\mu_t] - E\left[\frac{\mu_t}{\sigma_t^2}\right]E[\sigma_t^2]$, we obtain a relation between alpha and the dynamics of the price of risk

μ_t/σ_t^2 ,¹⁶

$$\alpha = -cov\left(\frac{\mu_t}{\sigma_t^2}, \sigma_t^2\right) \frac{c}{E[\sigma_t^2]}. \quad (8)$$

Thus, our α is a direct measure of the comovement between the price of risk and variance. In the case in which expected returns and volatility move together, that is, $\mu_t = \gamma\sigma_t^2$, we have $\alpha = 0$. Intuitively, by avoiding high-volatility times you avoid risk, but if the risk-return trade-off is strong you also sacrifice expected returns, leaving the volatility timing strategy with zero alpha.

In contrast, when expected returns are constant or independent of volatility, equation (8) implies $\alpha = c \frac{E[\mu_t]}{E[\sigma_t^2]} J_\sigma$, where $J_\sigma = \left(E[\sigma_t^2]E\left[\frac{1}{\sigma_t^2}\right] - 1\right) > 0$ is a Jensen's inequality term that is increasing in the volatility of volatility. This is because the more volatility varies, the more variation there is in the price of risk that the portfolio can capture. Thus, the alpha of our strategy is increasing in the volatility of volatility and the unconditional compensation for risk.

The profitability of our strategy can also be recast in terms of the analysis in Jagannathan and Wang (1996) because we are testing a strategy with zero conditional alpha using an unconditional model.¹⁷ The above results provide an explicit mapping between volatility-managed alphas and the dynamics of the price of risk for an individual asset.

¹⁶Formally, statements about the variance (and covariance) of a stochastic process in continuous time should be thought of as statements about the quadratic variation (or cross-variance) of these processes. It is exactly the fact that in continuous time the covariance between conditional means is of order dt^2 that allows us to obtain cleaner formulas in continuous time.

¹⁷See also the Internet Appendix, where we show how to explicitly recover the strength of the conditional relationship between risk and return from our strategy's alpha.

A. The Aggregate Price of Risk

While the above methodology applies to any return – even an individual stock – the results are only informative about the broader price of risk in the economy if applied to systematic sources of return variation. Intuitively, if a return is largely driven by idiosyncratic risk, then volatility timing will not be informative about the broader price of risk in the economy.¹⁸ In this section we show how our volatility-managed portfolios, when applied to systematic risk factors, recover the component of the aggregate price of risk variation driven by volatility.

Let $dR = [dR_1, \dots, dR_N]'$ be a vector of returns, with expected excess return μ_t^R and covariance matrix Σ_t^R . The empirical asset pricing literature shows that exposures to a few factors summarize expected return variation for a larger cross-section of assets and strategies captured by dR_t . We formalize our interpretation of this literature as follows:

ASSUMPTION 1: Let return factors $dF = [dF_1, \dots, dF_I]$, with dynamics given by μ_t and Σ_t , span the unconditional mean-variance frontier for static portfolios of $d\tilde{R} = [dR; dF_t]$ and the conditional mean-variance frontier for dynamic portfolios of $d\tilde{R}$. Define the process $\Pi_t(\gamma_t)$ as

$$\frac{d\Pi_t(\gamma_t)}{\Pi_t(\gamma_t)} = -r_t dt - \gamma_t' (dF_t - E_t[dF_t]). \quad (9)$$

Then there exists a constant price of risk vector γ^u such that $E[d(\Pi_t(\gamma^u)w\tilde{R})] = 0$ holds for any static weights w , and there is a γ_t^* process for which $E[d(\Pi_t(\gamma_t^*)w_t\tilde{R})] = 0$ holds for any dynamic weights w_t .

¹⁸See the Internet Appendix for an example.

This assumption says that unconditional exposures to these factors contain all relevant information to price the static portfolios R , but one may also need information on the price of risk dynamics to properly price dynamic strategies of these assets.

We focus on the case in which the factor covariance matrix is diagonal, $\Sigma_t = \text{diag}([\sigma_{1,t} \dots \sigma_{I,t}])$ (i.e., factors are uncorrelated), which empirically is a good approximation of the factors we study.¹⁹ In fact, many of the factors are constructed to be nearly orthogonal through double-sorting procedures. Given this structure, we can show how our strategy alphas allow one to recover the component of the price of risk variation driven by volatility.

IMPLICATION 1: *The factor i price of risk is $\gamma_{i,t}^* = \frac{\mu_{i,t}}{\sigma_{i,t}^2}$ and $\gamma_i^u = \frac{E[\mu_{i,t}]}{E[\sigma_{i,t}^2]}$. Decompose factor excess returns as $\mu_t = b\Sigma_t + \zeta_t$, where we assume $E[\zeta_t|\Sigma_t] = \zeta_t$. Let $\gamma_{i,t}^\sigma = E[\gamma_{i,t}^*|\sigma_{i,t}^2]$ be the component of the price of risk variation driven by volatility, and α_i be factor i 's volatility-managed alpha. Then*

$$\gamma_{i,t}^\sigma = \gamma_i^u + \frac{\alpha_i}{c_i} J_{\sigma,i}^{-1} \left(\frac{E[\sigma_{i,t}^2]}{\sigma_{i,t}^2} - 1 \right), \quad (10)$$

and the process $\Pi_t(\gamma_t^\sigma)$ is a valid SDF for $d\tilde{R}_t$ and volatility-managed strategies $w(\Sigma_t)$, that is, $E \left[d \left(\Pi_t(\gamma_t^\sigma) w(\Sigma_t) \tilde{R}_t \right) \right] = 0$.²⁰

Equation (10) shows how volatility-managed portfolio alphas allow us to reconstruct the variation in the price of risk due to volatility. The volatility-implied price of risk has two terms. The term γ^u is the unconditional price of risk, the price of risk that prices

¹⁹The Internet Appendix addresses the case in which factors are correlated.

²⁰Formally, $\gamma_t^\sigma = [\gamma_{1,t}^\sigma \dots \gamma_{I,t}^\sigma]$, and the strategies $w(\Sigma_t)$ must be adapted to the filtration generated by Σ_t , self-financing, and satisfy $E[\int_0^T ||w(\Sigma_t)\Sigma_t||^2 dt] < \infty$ (see Duffie (2010)).

static portfolios of returns dR_t . It is the term typically recovered in cross-sectional tests. The second is due to volatility. It increases the price of risk when volatility is low, with this sensitivity increasing in our strategy alpha. Thus, volatility-managed alphas allow us to answer the question of how much compensation for risk moves as volatility moves.

Tracking variation in the price of risk due to volatility can be important for pricing. Specifically, $\Pi(\gamma_t^\sigma)$ can price not only the original assets unconditionally, but also volatility-based strategies of these assets.²¹ Thus, volatility-managed portfolios allow us to get closer to the true price of risk process γ_t^* , and as a result, closer to the unconditional mean-variance frontier, a first-order economic object. In the Internet Appendix we show how one can implement the risk adjustment embedded in model $\Pi(\gamma_t^\sigma)$ by adding our volatility-managed portfolios as a factor.

We finish this section by providing a measure of how “close” $\Pi(\gamma_t^\sigma)$ gets to $\Pi(\gamma_t^*)$ relative to the constant price of risk model $\Pi(\gamma^u)$. Recognizing that $E[(d\Pi(\gamma_t^a) - d\Pi(\gamma_t^b)) dR_t]$ is the pricing error associated with using model b when prices are consistent with a , it follows that the volatility of the difference between models, $\mathcal{D}_{b-a} \equiv \text{Var}(d\Pi(\gamma_t^a) - d\Pi(\gamma_t^b))$, provides an upper bound on pricing error Sharpe ratios (see Hansen and Jagannathan

²¹For example, Boguth et al. (2011) argue that a large set of mutual fund strategies involve substantial volatility timing. Our volatility-managed portfolio provides a straightforward method to risk-adjust these strategies. This assumes of course that investors do indeed understand the large gain from volatility timing and nevertheless find it optimal not to trade.

(1991)). It is thus a natural measure of distance. For the single-factor case, we obtain

$$\mathcal{D}_{u-\sigma} = \left(\frac{\alpha}{c}\right)^2 E[\sigma_t^2] J_\sigma^{-1} \quad (11)$$

$$\mathcal{D}_{u-\zeta} = \frac{\text{Var}(\zeta_t)}{E[\sigma_t^2]} \quad (12)$$

$$\mathcal{D}_{u-*} = \left(\frac{\alpha}{c}\right)^2 E[\sigma_t^2] J_\sigma^{-1} + \frac{\text{Var}(\zeta_t)}{E[\sigma_t^2]} (J_\sigma + 1). \quad (13)$$

Equation (11) shows that the distance between models u and σ grows with alpha. In particular, it implies that the maximum excess Sharpe ratio decreases proportionally with the strategy alpha when you move from the constant price of risk model u to the model σ that incorporates variation in the price of risk driven by volatility. This is similar in spirit to Nagel and Singleton (2011), who derive general optimal managed portfolios based on conditioning information to test unconditional models against. Analogously, equation (12) accounts for variation in the expected return signal ζ_t but ignores volatility information. Equation (13) shows the total difference between the constant price of risk model u and the true $*$ model.

To have a sense of magnitudes, we assume that the market portfolio satisfies Assumption 1 and plug in numbers for the market portfolio. Notice that $\mathcal{D}_{u-\sigma}$ is the volatility-managed market's appraisal ratio squared, which measures the expansion of the MVE frontier for the managed strategy. We measure all the quantities in (11) to (13) but $\text{Var}(\zeta_t)$, which is tightly related to return predictability R^2 . We use the estimate from Campbell and Thompson (2008), who obtain a number around 0.06.²² We obtain $\mathcal{D}_{u-\sigma} = 0.33^2 =$

²²A range in this literature would put an upper bound at around 13% for the R^2 at the yearly horizon; see Kelly and Pruitt (2013). Notice also that $\text{Var}(\zeta_t)$ is actually below $\text{Var}(\mu_t)$, so these are strong upper

0.11, $\mathcal{D}_{u-\zeta} = 0.06$, and $\mathcal{D}_{u-*} = 0.11 + 0.06 * 3.2 = 0.29$. Accounting for only time-variation in volatility can reduce squared pricing error Sharpe ratios by approximately $0.11/0.29=38\%$, compared with $0.06/0.29=21\%$ for time-variation in expected returns, with the large residual being due to the multiplicative interaction between them.

The above results show that accounting for time-variation in the price of risk driven by volatility seems at least as important as, and perhaps even more important than, accounting for variation in the price of risk driven by expected returns.

IV. General Equilibrium Implications

We start this section by showing that the high Sharpe ratios of our volatility-managed portfolios pose a new challenge to leading macro-finance models. We then discuss potential economic mechanisms that could generate our findings.

A. Macro-Finance Models

Our empirical findings pose a challenge to macro-finance models that is statistically sharper than standard risk-return regressions. In fact, many equilibrium asset pricing models have largely ignored the risk-return trade-off literature, which runs regressions of future returns on volatility, because the results of that literature are ambiguous and statistically weak (see Glosten, Jagannathan, and Runkle (1993), Whitelaw (1994), Lundblad (2007), Lettau and Ludvigson (2003)).²³

bounds.

²³See also related work by Bollerslev et al. (2016) and Tang and Whitelaw (2011).

We assess the statistical power of our approach by studying the predictions of four leading equilibrium asset pricing models: the habits model (Campbell and Cochrane (1999)), long-run risk model (Bansal, Kiku, and Yaron (2012)), time-varying rare disasters model (Wachter (2013)), and intermediary-based asset pricing model (He and Krishnamurthy (2013)). Specifically, we calibrate each model according to the original papers and simulate stock market return data for a sample of equal length to our historical sample.

We first run a standard risk-return trade-off regression for the market portfolio

$$R_{mkt,t+1} - R_{f,t+1} = a + \gamma \hat{\sigma}_{mkt,t}^2 + \epsilon_{t+1} \quad (14)$$

in the data and in simulated data from each model. Results are shown in Figure 7, which provides a histogram of the estimated coefficient γ across simulations of each model and the actual point estimate from this regression in the data.

[Figure 7 about here]

We next construct our volatility-managed portfolios, exactly as described in Section I.B. We compute alphas and appraisal ratios in the model-simulated data and again compare to the actual data for the market portfolio.

The contrast between our approach and the return-forecasting approach is striking. All models frequently generate return histories consistent with the weak risk-return trade-off estimated in the data. However, no model comes close to reproducing our findings in terms of alphas or appraisal ratios. For example, Bansal and Yaron (2004) match the data in only 0.2% of the simulated samples. The other three models do even worse in match-

ing the alpha we observe in the data. These results indicate that our volatility-managed portfolios pose a fresh challenge to these models.

In these models alphas are either near zero or negative on average. From equation (8) this is equivalent to $cov(\gamma_t, \sigma_t^2) \geq 0$, where $\gamma_t = E_t[R_{t+1}]/\sigma_t^2$ can be thought of as the market effective risk-aversion. The models generally feature a weakly positive covariance between effective risk-aversion and variance because they typically have risk-aversion either increasing or staying constant in bad economic times when volatility is also high. The positive alphas we document empirically imply that this covariance is negative.

B. What Could Explain Our Results?

A definitive answer to this question is beyond the scope of this paper and left to future work. Nevertheless, we consider a few possibilities.

The easiest, but least plausible, explanation is that investors' willingness to take risk is negatively related to volatility. That is, investors choose not to time volatility because they are less risk-averse during high-volatility periods. A more nuanced explanation is that nontraded wealth becomes less volatile when financial market volatility is high. We also find this explanation unappealing, as volatility tends to be high in recessions when macroeconomic uncertainty is high. In the context of representative agent models, a plausible explanation is that volatility driven by learning about structural parameters might be priced differently than volatility driven by standard forms of risk (e.g, Veronesi (2000)).

One intuitive explanation for our results is that some investors are slow to trade. This

could explain why a sharp increase in realized volatility does not immediately lead to a higher expected return in the data. This explanation is also consistent with our impulse responses where expected returns rise slowly but the true expected volatility process rises and mean-reverts quickly in response to a variance shock. In line with this view, Nagel et al. (2016) find that higher-income households, which may be more sophisticated investors, seem to sell more quickly in response to increases in volatility in the 2008 crisis.

A final possibility is that the composition of shocks changes with volatility. In a companion paper (Moreira and Muir (2016)) we show that long-horizon investors may find volatility timing somewhat less beneficial if increases in volatility are driven by increases in discount rate volatility. That is, increases in volatility are due to an increase in the volatility of shocks that eventually mean-revert. Intuitively, increases in discount rate volatility increase the likelihood that an investor wakes up poorer tomorrow, but have no effect on the distribution of their wealth in the very long run. Quantitatively, Moreira and Muir (2016) show that because discount rate shocks seem to be very persistent in the data, even in the extreme case in which volatility is completely driven by discount rate volatility, investors with plausible investment horizons can still benefit somewhat from volatility timing. Thus, variation in the composition of shocks can reduce, but not solve, the puzzle. Furthermore, Moreira and Muir (2016) leave open the challenge of developing a plausible equilibrium mechanism whereby discount rate volatility is not tightly related to the level of discount rates.

We acknowledge that the above explanations need to be considered in more detail and analyzed quantitatively before we can evaluate their success. We leave this task to

future work.

V. Conclusion

Volatility-managed portfolios offer large risk-adjusted returns and are easy to implement in real time. Because volatility does not strongly forecast future returns, factor Sharpe ratios are improved by lowering risk exposure when volatility is high and increasing risk exposure when volatility is low. Our strategy runs contrary to conventional wisdom because it takes relatively less risk in recessions and crises yet still earns high average returns. We analyze both portfolio choice and general equilibrium implications of our findings. We find utility gains from volatility timing for mean-variance investors of around 65%, which is much larger than utility gains from timing expected returns. Furthermore, we show that our strategy performance is informative about the dynamics of effective risk-aversion, a key object for theories of time-varying risk premia.

Table I. Volatility-Managed Factor Alphas.

In Panel A We run time-series regressions of each volatility-managed factor on the non-managed factor $f_t^\sigma = \alpha + \beta f_t + \varepsilon_t$. The managed factor, f^σ , scales by the factor's inverse realized variance in the preceding month $f_t^\sigma = \frac{c}{RV_{t-1}^2} f_t$. In Panel B, we include the Fama-French three factors as additional controls in the regression. The data are monthly and the sample period is 1926 to 2015 for Mkt, SMB, HML, and Mom, 1963 to 2015 for RMW and CMA, 1967 to 2015 for ROE and IA, 1983 to 2015 for the FX carry factor, and 1929-2012 for BAB. Standard errors are in parentheses and adjust for heteroskedasticity. All factors are annualized in percent per year by multiplying monthly factors by 12.

| Panel A: Univariate Regressions | | | | | | | | | | |
|---|----------------------|----------------------|----------------------|----------------------|----------------------|----------------------|---------------------|----------------------|---------------------|-----------------------|

Table II. Mean-Variance Efficient Factors.

In Panel A we form unconditional mean-variance efficient (MVE) portfolios using various combinations of factors. These underlying factors can be thought of as the relevant information set for a given investor (e.g., an investor who only has the market available, or a sophisticated investor who also has value and momentum available). We then volatility time each of these MVE portfolios and report alphas from regressing the volatility-managed portfolio on the original MVE portfolio. The volatility-managed portfolio scales the portfolio by the inverse of the portfolios' realized variance in the previous month. We also report the annualized Sharpe ratio of the original MVE portfolio and the appraisal ratio of the volatility-managed MVE portfolio, which tells us how much the volatility-managed portfolio increases investors' Sharpe ratio relative to no volatility timing. The factors considered are the Fama-French three- and five-factor models, the momentum factor, and the Hou et al. (2014) four factors (HXZ). Panel B reports the alphas of these MVE combinations in subsamples where we split the data into three 30-year periods. Note that some factors are not available in the early sample.

| Panel A: Mean-Variance Efficient Portfolios (Full Sample) | | | | | | | |

| α : 1986-2015 | 4.22 (1.66) | 5.66 (1.74) | 4.98 (0.95) | 1.88 (0.41) | 2.65 (0.47) | 3.03 (0.50) | 3.24 (0.57) |

Table III. Recession Betas by Factor.

In this table we regress each scaled factor on the original factor and we include recession dummies $1_{rec,t}$ using NBER recessions, which we interact with the original factors; $f_t^\sigma = \alpha_0 + \alpha_1 1_{rec,t} + \beta_0 f_t + \beta_1 1_{rec,t} \times f_t + \varepsilon_t$. This gives the relative beta of the scaled factor conditional on recessions compared to the unconditional estimate. Standard errors are in parentheses and adjust for heteroskedasticity. We find that $\beta_1 < 0$, so that betas for each factor are relatively lower in recessions.

Table IV. Transaction Costs of Volatility Timing.

In this table we evaluate our volatility timing strategy for the market portfolio when including transaction costs. We consider alternative strategies that still capture the idea of volatility timing but significantly reduce trading activity implied by our strategy. Specifically, we consider using inverse volatility instead of variance, using expected rather than realized variance, and using our original inverse realized variance but restricting risk exposure to be below 1 (i.e., no leverage) or 1.5. For expected variance, we run an AR(1) for log variance to form our forecast. We report the average absolute change in monthly weights ($|\Delta w|$), expected return, and alpha of each of these alternative strategies. We then report the alpha when including various trading costs. The 1bp cost comes from Fleming, Kirby, and Ostdiek (2003), the 10bps comes from Frazzini, Israel, and Moskowitz (2015) when trading about 1% of daily volume, and the next column adds an additional 4bps to account for transaction costs increasing in high-volatility episodes. Specifically, we use the slope coefficient of transaction costs on VIX from Frazzini, Israel, and Moskowitz (2015) and evaluate this impact on a move in VIX from 20% to 40%, which represents the 98th percentile of VIX. Finally, the last column backs out the implied trading costs in basis points needed to drive our alphas to zero in each of the cases.

| w | Description | $ \Delta w $ | $E[R]$ | α | α After Trading Costs | | | |
|--|-------------------|--------------|--------|----------|------------------------------|-------|-------|------------|
| | | | | | 1bps | 10bps | 14bps | Break Even |
| $\frac{1}{RV_t^2}$ | Realized Variance | 0.73 | 9.47% | 4.86% | 4.77% | 3.98% | 3.63% | 56bps |
| $\frac{1}{RV_t}$ | Realized Vol | 0.38 | 9.84% | 3.85% | 3.80% | 3.39% | 3.21% | 84bps |
| $\frac{1}{E_t[RV_{t+1}^2]}$ | Expected Variance | 0.37 | 9.47% | 3.30% | 3.26% | 2.86% | 2.68% | 74bps |
| $\min\left(\frac{c}{RV_t^2}, 1\right)$ | No Leverage | 0.16 | 5.61% | 2.12% | 2.10% | 1.93% | 1.85% | 110bps |
| $\min\left(\frac{c}{RV_t^2}, 1.5\right)$ | 50% Leverage | 0.16 | 7.18% | 3.10% | 3.08% | 2.91% | 2.83% | 161bps |

Table V. Volatility Timing and Leverage.

Panel A shows several alternative volatility-managed strategies and the corresponding alphas, Sharpe ratios, and distribution of weights used in each strategy. The alternative strategies include using inverse volatility instead of variance, using expected rather than realized variance, and using inverse realized variance but restricting risk exposure to be below 1 (i.e., no leverage) or 1.5. For expected variance, we run an AR(1) for log variance to form our forecast. In particular, we focus on upper percentiles of weights to determine how much leverage is typically used in each strategy. In each case we focus on the market portfolio. In Panel B, we consider strategies that use embedded leverage instead of actual leverage for the market portfolio. Specifically, we look at investing in a portfolio of options on the S&P500 index using either just call options or both calls and puts. The portfolio is an equal-weighted average of six in-the-money call options with maturities of 60 and 90 days and moneyness of 90, 92.5, and 95. The beta of this portfolio is 7. Any time our strategy prescribes leverage to achieve high beta, we invest in this option portfolio to achieve our desired beta. We then compare the performance of the embedded leverage-volatility-managed portfolio to the standard volatility-managed portfolio. Finally, we consider an option strategy that also sells in-the-money puts (with the same moneyness as before) and buys calls to again achieve our desired beta. The sample used for Panel B is April 1986 to January 2012 based on data from Constantinides et al. (2013).

| Panel A: Weights and Performance for Alternative Volatility-Managed Portfolios | | | | | | | | |
|--|---------------------|----------------|--------|-----------|-----------------------------|------|------|------|
| w_t | Description | α | Sharpe | Appraisal | Distribution of Weights w | | | |
| | | | | | P50 | P75 | P90 | P99 |
| $\frac{1}{RV_t^2}$ | Realized Variance | 4.86 (1.56) | 0.52 | 0.34 | 0.93 | 1.59 | 2.64 | 6.39 |
| $\frac{1}{RV_t}$ | Realized Volatility | 3.30 (1.02) | 0.53 | 0.33 | 1.23 | 1.61 | 2.08 | 3.36 |
| $\frac{1}{E_t[RV_{t+1}^2]}$ | Expected Variance | 3.85 (1.36) | 0.51 | 0.30 | 1.11 | 1.71 | 2.38 | 4.58 |
| $\min\left(\frac{c}{RV_t^2}, 1\right)$ | No Leverage | 2.12 (0.71) | 0.52 | 0.30 | 0.93 | 1 | 1 | 1 |
| $\min\left(\frac{c}{RV_t^2}, 1.5\right)$ | 50% Leverage | 3.10 (0.98) | 0.53 | 0.33 | 0.93 | 1.5 | 1.5 | 1.5 |

| Panel B: Embedded Leverage Using Options: 1986-2012 | | | | |
|---|--------------|------------|-----------------------------------|--------------|
| | Buy and Hold | Vol Timing | Vol Timing With Embedded Leverage | |
| | | | Calls | Calls + Puts |
| Sharpe Ratio | 0.39 | 0.59 | 0.54 | 0.60 |
| α | – | 4.03 | 5.90 | 6.67 |
| $s.e.(\alpha)$ | – | (1.81) | (3.01) | (2.86) |
| β | – | 0.53 | 0.59 | 0.59 |
| Appraisal Ratio | – | 0.44 | 0.39 | 0.46 |

Table VI. Time-Series Alphas Controlling for Risk Parity Factors.

In this table we run time-series regressions of each volatility-managed factor on the non-managed factor plus a risk parity factor based on Asness, Frazzini, and Pedersen (2012). The risk parity factor is given by $RP_{t+1} = b_t' f_{t+1}$, where $b_{i,t} = \frac{1/\tilde{\sigma}_t^i}{\sum_i 1/\tilde{\sigma}_t^i}$ and f is a vector of pricing factors. Volatility is measured on a rolling three-year basis following Asness, Frazzini, and Pedersen (2012). We construct this risk parity portfolio for various combinations of factors. We then regress our volatility-managed MVE portfolios from Table II on both the static MVE portfolio and the risk parity portfolio formed using the same factors, f , that make up the MVE portfolio. We find that our alphas are unchanged from those found in the main text. In the last column, we report the alpha for the volatility-managed betting against beta (BAB) portfolio to show that our time-series volatility timing is different from cross-sectional low-risk anomalies and that in fact both can be combined together. Standard errors are in parentheses and adjust for heteroskedasticity. All factors are annualized in percent per year by multiplying monthly factors by 12.

| | (1) Mkt | (2) FF3 | (3) FF3 Mom | (4) FF5 | (5) FF5 Mom | (6) HXZ | (7) HXZ Mom | (8) BAB $^\sigma$ |

Table VII. Normalizing by Common Volatility.

In this table we construct volatility-managed strategies for each factor using the first principal component of realized variance across all factors. Each factor is thus normalized by the same variable, in contrast to our main results where each factor is normalized by that factor's past realized variance. We run time-series regressions of each managed factor on the nonmanaged factor.

| | (1) Mkt $^\sigma$ | (2) SMB $^\sigma$ | (3) HML $^\sigma$ | (4) Mom $^\sigma$ | (5) RMW $^\sigma$ | (6) CMA $^\sigma$ | (7) FX $^\sigma$ | (8) ROE $^\sigma$ | (9) IA $^\sigma$ |

| R^2 | 0.42 | 0.45 | 0.36 | 0.33 | 0.44 | 0.51 | 0.64 | 0.47 | 0.56 |
| RMSE | 49.31 | 28.74 | 33.87 | 46.57 | 19.11 | 16.67 | 18.49 | 22.13 | 15.06 |

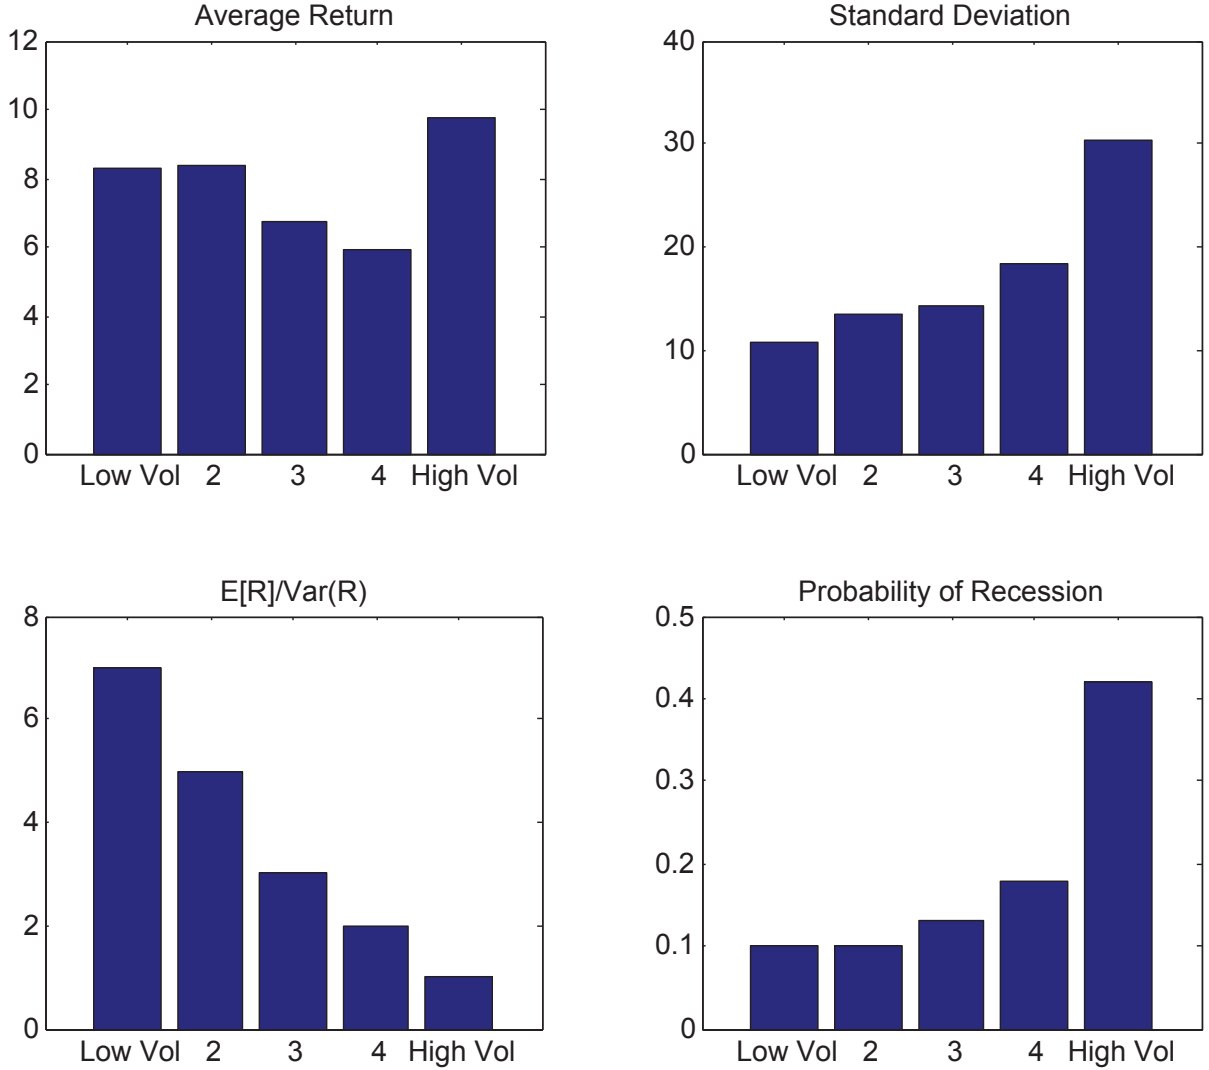

Figure 1. Sorts on the previous month's volatility. We use the monthly time series of realized volatility to sort the following month's returns into five buckets. The lowest, "low vol," looks at the properties of returns over the month *following* the lowest 20% of realized volatility months. We show the average return over the next month, the standard deviation over the next month, and the average return divided by variance. Average return per unit of variance represents the optimal risk exposure of a mean-variance investor in partial equilibrium, and also represents "effective risk-aversion" from a general equilibrium perspective (i.e., the implied risk aversion, γ_t , of a representative agent needed to satisfy $E_t[R_{t+1}] = \gamma_t \sigma_t^2$). The last panel shows the probability of a recession across volatility buckets by computing the average of an NBER recession dummy. Our sorts should be viewed as analogous to standard cross-sectional sorts (i.e., book-to-market sorts) but are instead done in the time series using lagged realized volatility.

Figure 2. Time series of volatility by factor. This figure plots the time series of the monthly volatility of each individual factor. We emphasize the common co-movement in volatility across factors and the fact that volatility generally increases for all factors in recessions. Light shaded bars indicate NBER recessions and show a clear business cycle pattern in volatility.

Figure 3. Cumulative returns to volatility timing for the market return. The top panel plots the cumulative returns to a buy-and-hold strategy versus a volatility timing strategy for the market portfolio from 1926 to 2015. The y-axis is on a log scale and both strategies have the same unconditional monthly standard deviation. The lower left panel plots rolling one-year returns from each strategy and the lower right panel shows the drawdown of each strategy.

Figure 4. Utility benefits and leverage constraints. We plot the empirical percentage utility gain $\Delta U\%$ for a mean-variance investor going from a buy-and-hold portfolio to a volatility-managed portfolio for different levels of risk-aversion and for various constraints on leverage. Specifically, $U = E[w_t R_{t+1}] - \frac{1}{2}\gamma \text{var}(w_t R_{t+1})$. We compute the unconditional target buy-and-hold weight (i.e., the optimal portfolio for an investor who does not change risk exposure over time) as $w = \frac{1}{\gamma} \frac{\mu}{\sigma^2}$ and volatility-managed weights as $w_t = \frac{1}{\gamma} \frac{\mu}{\sigma_t^2}$. The x-axis denotes the targeted buy-and-hold weight w as we vary investor risk-aversion γ and represents the desired unconditional weight in the risky asset. The solid line shows the percentage increase in utility $(U(w_t)/U(w) - 1)$ when our weights, w_t , are unrestricted and illustrates that in this case the utility gain does not depend on risk-aversion. The dot-dashed and dashed lines impose leverage constraints of zero leverage and 50% leverage (consistent with a standard margin constraint), respectively. We evaluate the utility percentage increases $U(\min(w_t, \bar{w}))/U(\min(w, \bar{w})) - 1$ with $\bar{w} = \{1, 1.5\}$. Numbers presented are for the market return.

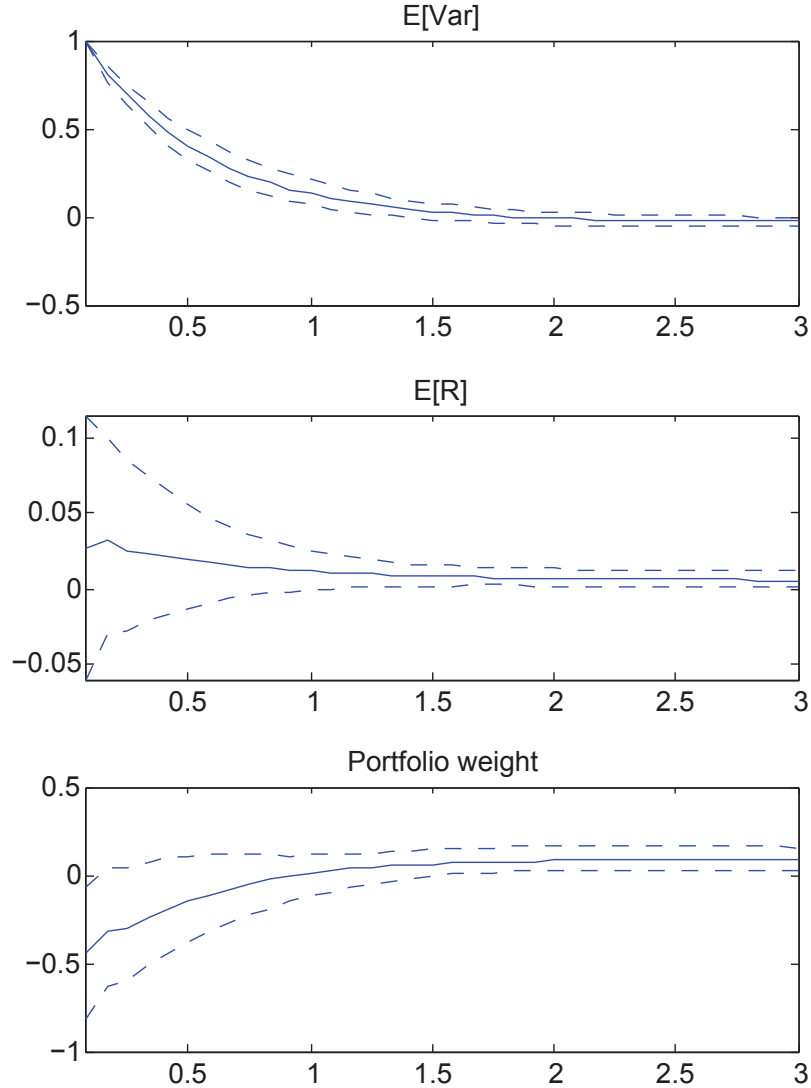

Figure 5. Dynamics of the risk-return trade-off. The figure plots the impulse response of the expected variance and expected return of the market portfolio for a shock to the realized variance. The x-axis is in years. The bottom panel gives the portfolio choice implications for a mean-variance investor who sets their risk exposure proportional to $E_t[R_{t+1}]/var_t[R_{t+1}]$. The units are percentage deviations from their average risk exposure. We compute impulse responses using a VAR of realized variance, realized returns, and the cyclically adjusted price-to-earnings ratio (CAPE) from Robert Shiller. We include two lags of each variable. Bootstrapped 95% confidence bands are given in dashed lines.

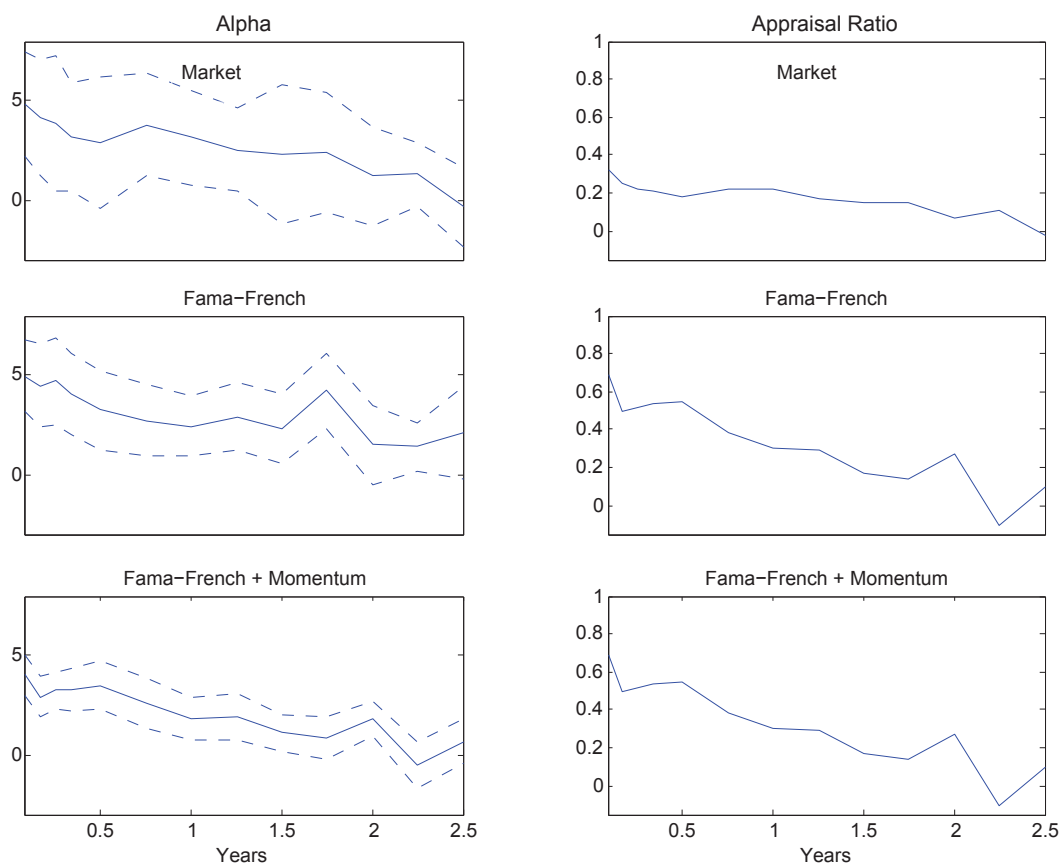

Figure 6. Results by re-balancing period. This figure plots alphas and appraisal ratios by re-balancing period given in years on the x-axis. We compute scaled portfolios using the inverse of monthly realized variance and plot the alphas and appraisal ratios for different rebalancing horizons. All numbers are annualized for ease of interpretation. The top two panels do this for the market return, the middle panels use the MVE portfolio formed from the Fama-French three factors, and the bottom panels add the momentum factor. We include 90% confidence bands for alphas in dashed lines.

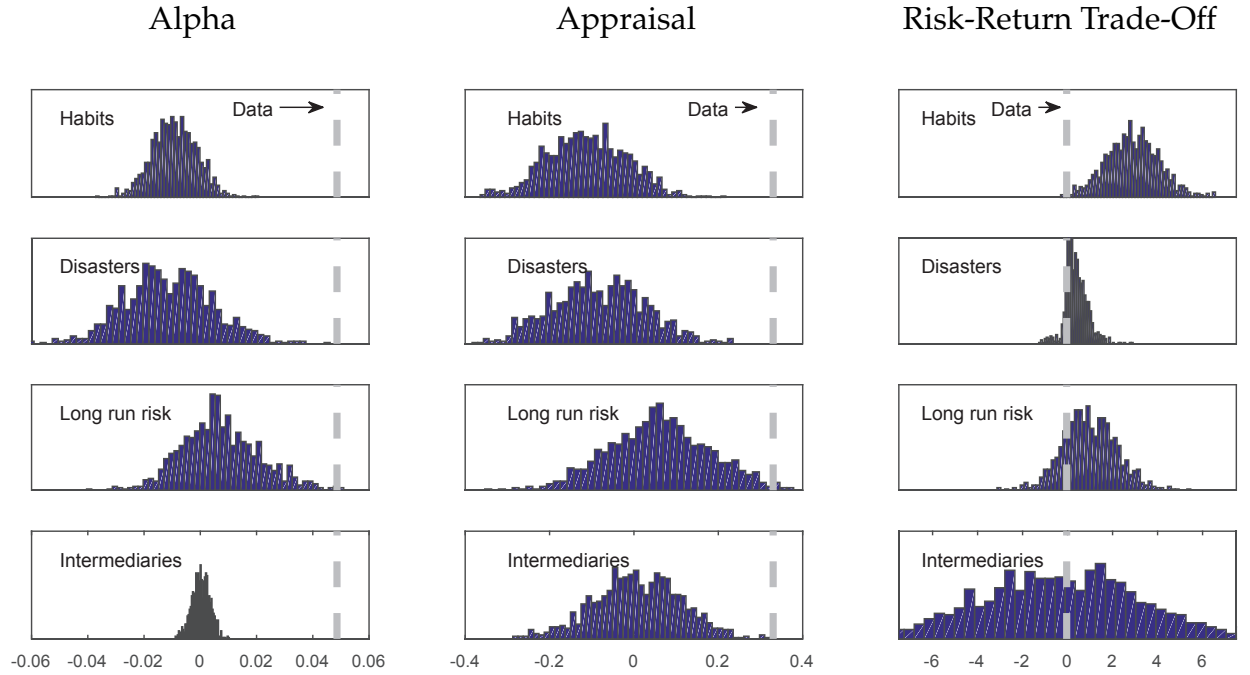

Figure 7. Equilibrium models and volatility timing. The figure plots the distribution of moments recovered from 1,000 simulations of 100-year samples for the different equilibrium models. The dashed line shows the point estimate in the historical sample. The left panels show the alpha of the volatility-managed strategy, the middle panels the appraisal ratio of the volatility-managed strategy, and the right panels the slope coefficient in a predictive regression of the market excess return on the previous month's realized variance. Moments are recovered by replicating in the simulations exactly the same exercise as in the data. In the first row we show the habits model of Campbell and Cochrane (1999), in the second row the rare disaster model of Wachter (2013), in the third row the long-run risk model of Bansal and Yaron (2004), and in the last row the intermediary-based model of He and Krishnamurthy (2013). Simulations are done using the original papers' parameter calibrations.

Internet Appendix for “Volatility-Managed Portfolios”

ALAN MOREIRA and TYLER MUIR*

March 5, 2017

This document has two main sections. In section I, we extend our empirical analysis in several fronts. In section II, we provide proofs and a few extensions to the theoretical framework presented in Section III of the main text.

I. Additional Empirical Results

This subsection performs various robustness checks of our main result. Specifically, we use a measure of conditional variance instead of realized variance in our portfolio and find similar results, extend the analysis to international data, evaluate potential risk-based explanations for our findings, study how our strategy performs with respect to alternative performance metrics, evaluate to what extent our strategy generates option-like payoffs, and finally alternative sub-samples.

A. *Additional Evidence: Credit and Term Premia*

Table IA. I uses monthly data from Asvanunt and Richardson (2016) on credit risk premia and term premia for the United States from 1926-2014. The credit risk factor is formed from corporate bond returns which are duration-matched to government bonds.

*Moreira, Alan and Muir, Tyler, Internet Appendix for “Volatility-Managed Portfolios”, *Journal of Finance* [DOI STRING]. Please note: Wiley-Blackwell is not responsible for the content or functionality of any supporting information supplied by the authors. Any queries (other than missing material) should be directed to the authors of the article.

The credit risk factor thus captures only credit risk, but no term premium. The term premium factor is formed from long versus short maturity government bonds. We refer the reader to Asvanunt and Richardson (2016) for specific details. We only have monthly data for each series, hence we form our volatility-managed portfolios for these factors using the variance of the past 18 months of monthly returns to scale the factors. This is in contrast to the daily returns used in the main text. The volatility-managed credit factor has a statistically significant alpha of 1.5% per annum (for reference, the average return of the credit risk factor is 2.2% per annum) and an annualized appraisal ratio of 0.4. The volatility-managed term premium has an alpha of 1.25% which is not significant yet still economically fairly large. Thus, we conclude that there is strong evidence that volatility timing improves the Sharpe ratio for credit, but only weak evidence that it does so for the term premium.

B. Using Expected Variance Instead of Realized Variance

Table IA. II shows the results when, instead of scaling by past realized variance, we scale by the expected variance from our forecasting regressions where we use three lags of realized log variance to form our forecast. This offers more precision but comes at the cost of assuming that an investor could forecast volatility using the forecasting relationship in real time. As expected, the increased precision generally increases significance of alphas and increases appraisal ratios. We favor using the realized variance approach because it does not require a first stage estimation and has a clear appeal from the perspective of practical implementation. Other variance forecasting methods behave similarly, see, for example Andersen and Bollerslev (1998).

C. *International Data*

As an additional robustness check, we show that our results hold for the stock market indices of 20 OECD countries. On average, the volatility-managed version of the index has an annualized Sharpe ratio that is 0.15 higher than a passive buy-and-hold strategy. Moreover, the volatility-managed index has a higher Sharpe ratio than the passive strategy in 80% of cases. These results are detailed in Figure IA. 1. Note that this is a strong condition – a portfolio can have positive alpha even when its Sharpe ratio is below that of the nonmanaged factor.

D. *Other Risk Based Explanations*

Variance risk premia: Because our strategy aggressively times volatility, a reasonable concern is that our strategy's high Sharpe ratio is due to a large exposure to variance shocks, which would require a high risk premium (Ang et al. (2006b), Carr and Wu (2009)). However, it turns out that our strategy is much less exposed to volatility shocks than the buy-and-hold strategy. This follows from the fact that the volatility of volatility is higher when volatility is high. Because our strategy takes less risk when volatility is high, it is also less sensitive to volatility shocks.

Downside risk: In unreported results, we find that the downside betas of our strategy following the methodology in Lettau, Maggiori, and Weber (2014) are always substantially lower than unconditional betas. For example, for the volatility-managed market return, the downside beta we estimate is 0.11 and is not significantly different from zero. Thus, alphas would be even larger if we evaluated them relative to the downside risk CAPM (Ang, Chen, and Xing (2006a), Lettau, Maggiori, and Weber (2014)). Intuitively, periods of very low market returns are typically preceded by periods of high volatility when our strategy has a low risk exposure.

Disaster risk: For disaster risk to explain our findings, our volatility-managed portfo-

lio would have to be more exposed to disaster risk than the static portfolio. Because empirically, macro-economic disasters unfold over many periods (Nakamura et al. (2013)) and feature above-average financial market volatility (Manela and Moreira (2016)), the volatility timing strategy tends to perform better during disaster events than the static counterpart. This is further supported by the fact that our strategy takes less risk during the Great Depression and the recent financial crisis (see Figure 3 of the main text), the two largest consumption declines in our sample.

Jump risk: Jump risk is the exposure to sudden market crashes. To the extent that crashes after low-volatility periods happen frequently, our strategy should exhibit much fatter tails than the static strategy, yet we do not see this when analyzing the unconditional distribution of the volatility-managed portfolios. Overall, crashes during low-volatility times are not frequent enough (relative to high-volatility times) to make our volatility-managed portfolio more exposed to jump risk than the static buy-and-hold. If anything, jumps seem to be much more likely when volatility is high (Bollerslev and Todorov (2011)), suggesting that our strategy is less exposed to jump risk than the buy-and-hold portfolio.

Betting against beta controls: Table IA. III gives the alphas of our volatility-managed factors when we include the BAB factor of Frazzini and Pedersen (2014). As we can see from Table IA. III, the results are identical to those in the main text. Moreover, the BAB factor does not appear significant, which means that it is not strongly correlated with our volatility-managed portfolios. This again reinforces the point that our strategy is quite different from this cross-sectional low-risk anomaly.

Multivariate analysis: We study whether some of the single-factor volatility timing strategies are priced by other aggregate factors. Consistent with Table II, Tables IA. IV and IA. V show that the scaled factors expand the mean-variance frontier of the existing factors because the appraisal ratio of HML, RMW, and Mom are positive and large when

including all factors. Notably, the alpha for the scaled market portfolio is lower when we include all factors. Thus, the other asset pricing factors, specifically momentum, contain some of the pricing information of the scaled market portfolio. For an investor who only has the market portfolio available, the univariate results are the appropriate benchmark; in this case, the volatility-managed market portfolio does have a large alpha. For the multivariate results (i.e., for an investor who has access to all factors) the relevant benchmark is the MVE portfolio, or “tangency portfolio,” since this is the portfolio investors with access to these factors will hold (within the set of static portfolios). We find that the volatility-managed version of each of the different MVE portfolios has a substantially higher Sharpe ratio and a large positive alpha with respect to the static factors.

E. An Alternative Performance Measure and Simulation Exercises

So far, we have focused on time-series alphas, Sharpe ratios, and appraisal ratios as our benchmark for performance evaluation. This section considers alternative measures and discusses some statistical concerns. We also conduct simulations to better evaluate our results.

In our simulations, we consider a world in which the price of risk is constant, $E_t[R_{t+1}] = \gamma \text{Var}_t[R_{t+1}]$, and choose parameters to match the average equity premium, average market standard deviation, and volatility of the market standard deviation. We model volatility as lognormal and returns as conditionally lognormal. Using these simulations we can ask, if the null that the risk-return trade-off is strong were true, what is the probability we would see the empirical patterns we document in the data (alphas, Sharpe ratios, etc.).

First, we study the manipulation-proof performance measure (henceforth MPPM) of Goetzmann et al. (2007). This measure is useful because, unlike alphas and Sharpe ratios, it can not be manipulated to produce artificially high performance. This manipulation could be done intentionally by a manager, say by decreasing risk exposure after experi-

encing a string of lucky returns, or through a type of strategy that uses highly non-linear payoffs. Essentially, the measure is based on the certainty equivalent for a power utility agent with risk-aversion ranging from 2 to 4 and evaluates their utility directly. We choose risk aversion of 3, although our results are not sensitive to this value. We find the market MPPM to be 2.48% and the volatility-managed market portfolio MPPM to be 4.33%, with the difference between the two 1.85% per year. This demonstrates that even under this alternative test that overcomes many of the potential shortcomings of traditional performance measures, we find that our volatility-managed strategy beats the buy-and-hold portfolio.

It is useful to consider the likelihood of this finding in relation to the null hypothesis that the price of risk is constant. In our simulations, we can compute the MPPM measure of the scaled market portfolio and compare it to the market portfolio MPPM. We find that the volatility-managed MPPM beats the market MPPM measure only 0.2% of the time. Hence, if the price of risk is not moving with volatility, it is highly unlikely that the MPPM measure would favor the volatility-managed portfolio. Using these simulations, we can also ask what is the likelihood that we would observe an alpha as high as we see in the data. The median alpha in our simulations with a constant price of risk is about 10bps and the chance of seeing an alpha as high as we see empirically (4.86%) is essentially zero.

F. Are Volatility-Managed Portfolios Option Like?

At least since Black and Scholes (1973), it has been well known that under some conditions option payoffs can be replicated by dynamically trading the reference asset. Since our strategy is dynamic, a plausible concern is that our strategy might be replicating option payoffs. A large literature discusses potential issues with evaluating strategies that have a strong option-like return profile.

We discuss each of the potential concerns and explain why it does not apply to our

volatility-managed portfolios. First, a linear asset pricing factor model where a return is a factor implies a stochastic discount factor that can be negative for sufficiently high factor return realizations (Dybvig and Ingersoll (1982)). Thus, there are states with a negative state price, which implies an arbitrage opportunity. A concern is that our strategy may be generating alpha by implicitly selling these negative state-price states. However, empirically this cannot be the source of our strategy alpha, as the implied stochastic discount factor is always positive in our sample.¹

Second, the nonlinearity of option-like payoffs can make the estimation of our strategy's beta challenging. Because some events happen only with very low probability, sample moments are potentially very different from population moments. This concern is much more pronounced for short samples. For example, most option and hedge fund strategies for which such biases are shown to be important have no more than 20 years of data. However, we have 90 years of data for the market portfolio. In Figure IA. 2 we also look at kernel estimates of the buy-and-hold and volatility-managed factor return distributions. No clear pattern emerges; if anything, the volatility-managed portfolio appears to have less mass on the left tail for some portfolios.

Third, another concern is that our strategy loads on high-price-of-risk states. For example, strategies that implicitly or explicitly sell deep out-of-the-money puts can capture the expected return resulting from the strong smirk in the implied volatility curve. Note that our strategy reduces risk exposure after a volatility spike, which is typically associated with low return realizations, while one would need to increase exposure following a low return realization to replicate the sale of a put option. Mechanically our strategy does exactly the opposite of what a put-selling strategy would call for. This also implies that our strategy will typically have less severe drawdowns than the static portfolio, which

¹For example, for the market factor the implied SDF can be written as $\approx 1/R_t^f - b(R_{t+1}^m - R_t^f)$, where empirically $b = E[R_{t+1}^m - R_t^f] / \text{Var}(R_t^e) \approx 2$. In our sample the highest return realization is 38%, so the SDF is never negative.

accords with our Figure 3.

A more general way of addressing the concern that our strategy alpha is due to its option-like returns is to use the manipulation proof performance measure (MPPM) proposed by Goetzmann et al. (2007). We find that the volatility-managed MPPM is 75% higher than the market MPPM. Using simulations we show that a volatility-managed portfolio would beat the market (as measured by MPPM) only 0.2% of the time if the risk-return trade-off was constant. This again shows that our strategy increases Sharpe ratios simply by avoiding high risk times and does not load on other unwanted risks.

Overall, there is no evidence that our volatility-managed portfolios generate option-like returns.

G. Additional Results on Subsamples

In addition to showing results for discreet subsamples in the main text, we provide rolling 30-year window alphas for our strategy in Figure IA. 3. We do this only for the market return. Consistent with our formula for alphas in the main text, we find that our strategy is most profitable during relatively high-volatility periods. This is due in large part to volatility varying the most during these subsamples. In subsamples where volatility does not vary much, the strategy weight is very close to a static buy-and-hold weight, and hence it is not able to increase Sharpe ratios relative to the buy-and-hold portfolio or generate alpha.

II. Theoretical Framework: Proofs and Extensions

A. Conditional Risk-Return Trade-off

We decompose variation in expected returns in a component due to volatility and an orthogonal component, $\mu_t = b\sigma_t^2 + \zeta_t$, for a constant b . We assume that the process ζ_t satisfies $E[\zeta_t|\sigma_t] = E[\zeta_t]$. The coefficient b represents the conditional risk-return trade-off.

We then have

$$\alpha = c(E[\sigma_t^2]E[1/\sigma_t^2] - 1)(\gamma - b), \quad (\text{IA. 1})$$

where alpha is positive if and only if $b < \gamma$, which means that the conditional risk-return trade-off is weaker than the unconditional risk-return trade-off. Moreover, the weaker the conditional risk-return trade-off, b , the higher the alpha.

B. Individual Stocks

Consider a simple example in which the CAPM holds, and the market portfolio return given by dF_t has constant expected returns and variance. Consider a individual stock with returns $dR_t = (r_t dt + \mu_{R,t})dt + \beta_R(dF_t - E_t[dF_t]) + \sigma_{R,t}dB_{R,t}$, where $dB_{R,t}$ shocks are not priced. We have that the volatility-managed alpha is

$$\alpha_R \propto -cov\left(\sigma_{R,t}^2, \frac{1}{\beta_R^2 \sigma_F^2 + \sigma_{R,t}^2}\right), \quad (\text{IA. 2})$$

which is positive (negative) if $\beta_R > 0$ ($\beta_R < 0$), but CAPM alphas are always zero.

While volatility timing can “work” for any asset with positive expected returns for which volatility is forecastable but does not predict returns, the alphas become economically interesting when studying systematic factors.

C. Proof of Implication 1

The fact that $\Pi(\gamma^u)$ must price factors F unconditionally immediately implies that $\gamma_i^u = E[\mu_{i,t}]/E[\sigma_{i,t}]$. Similarly, the fact that $\Pi(\gamma_i^*)$ must price factors F conditionally implies that $\gamma_{i,t}^* = \mu_{i,t}/\sigma_{i,t}$. We can thus write $\gamma_{i,t}^* = b + \zeta_t/\sigma_{i,t}$, with conditional expectation given by $E[\gamma_{i,t}^*|\Sigma_t] = b + E[\zeta_t]/\sigma_{i,t}$.

We now use result (IA. 1) to substitute out b and $E[\zeta_t]$. Specifically, we use that

$$b = \gamma_i^u - \alpha_i(c_i J_{\sigma,i})^{-1} \quad (\text{IA. 3})$$

$$E[\zeta_t] = E[\mu_{i,t}] - bE[\sigma_{i,t}^2] \quad (\text{IA. 4})$$

to obtain equation (10).

Now we show that the SDF $\Pi(\gamma_t^\sigma)$ prices all volatility-based strategies. We need to show that $E \left[d \left(\Pi_t(\gamma_t^\sigma) w(\Sigma_t) \tilde{R}_t \right) \right] = 0$, which is equivalent to

$$E \left[d \left(\Pi_t(\gamma_t^\sigma) w(\Sigma_t) \tilde{R}_t \right) \right] = E[w(\Sigma_t) \mu_t] - E[\gamma_t^\sigma (dF_t - E_t[\cdot]) w(\Sigma_t) \tilde{R}_t] \quad (\text{IA. 5})$$

Using the fact that factors are on the conditional mean-variance frontier, it is sufficient to show that the expression holds for the factors themselves. Furthermore, it is sufficient to show that the pricing equation holds for each portfolio conditional on Σ_t information.

This yields

$$E \left[d \left(\Pi_t(\gamma_t^\sigma) F_t \right) | \Sigma_t \right] = E[\mu_t | \Sigma_t] - E[\gamma_t^\sigma (dF_t - E_t[dF_t]) dF_t | \Sigma_t] \quad (\text{IA. 6})$$

$$= b \Sigma_t + E[\zeta_t] - \gamma_t^\sigma \Sigma_t \quad (\text{IA. 7})$$

$$= b \Sigma_t + E[\zeta_t] - (b + E[\zeta_t] \Sigma_t^{-1}) \Sigma_t \quad (\text{IA. 8})$$

$$= 0, \quad (\text{IA. 9})$$

where in the last line we use the fact that $\gamma_{i,t}^\sigma = E[\gamma_{i,t}^* | \Sigma_t] = b + E[\zeta_t] / \sigma_{i,t}$. This proves Implication 1.

D. Spanning the Unconditional Mean-Variance Frontier with Volatility-Managed Portfolios

The price of risk γ_t^σ is also the unconditional MVE portfolio from the perspective of an investor who can measure time-variation in volatility but not variation in ζ_t . The price of risk process can be represented with constant positions on the buy-and-hold factors and the volatility-managed factors.

IMPLICATION 1: *The unconditional MVE portfolio spanned by conditional information on volatility can be replicated by a constant position of the factors and the volatility-managed factors $[dF; dF^\sigma]$,*

$$E[w_i^*(\mu_t, \Sigma_t) | \Sigma_t] \propto \left[\gamma_i^u - \frac{\alpha_i}{c_i} J_{\sigma,i}^{-1}; \frac{\alpha_i}{c_i} J_{\sigma,i}^{-1} \frac{E[\sigma_{i,t}^2]}{c_i} \right]. \quad (\text{IA. 10})$$

These weights are simple functions of our strategy alpha. Assuming the market portfolio is on the conditional mean-variance frontier, we can plug in numbers for the market portfolio to get a sense of magnitudes. We get $[0.14; 0.86]$ for the weights on the market and the volatility-managed market portfolio. Our volatility-managed portfolio gets close to being unconditionally MVE because the relationship between return and volatility is so weak.

E. Correlated Factors

Our approach can be easily extended to the case in which factors are correlated. Let the factors' variance-covariance matrix be block-diagonal: it can be decomposed into N blocks as follows $\Sigma_t \Sigma_t' = \text{diag} \left(\left[H_1 \sigma_{1,t}^2, \dots, H_N \sigma_{N,t}^2 \right] \right)$, where $\sigma_{n,t}^2$ are scalars, and H_n are constant full-rank matrixes.

Given this factor structure in factor variances (see Section II.E of the main text to see that this is a good description of the data), we can apply our analysis to "block-specific" MVE portfolios constructed as follows. For block n , let $df_{n,t}$ be the vector of factor returns and $\mu_{n,t}$ be the vector of expected excess returns. Then the MVE portfolios are given by $df_{n,t}^{MVE} \equiv rdt + \mu_{n,t}' H_n^{-1} (df_{n,t} - rdt)$, which is exactly the procedure we follow in Section I.E of the main text.

Table IA. I. Volatility-Managed Factor Alphas.

We run time-series regressions of each volatility-managed factor on the nonmanaged factor $f_t^\sigma = \alpha + \beta f_t + \varepsilon_t$. The managed factor, f^σ , scales by the factor's inverse realized variance computed using the preceding 18 months of data $f_t^\sigma = \frac{c}{RV_{t-1}^2} f_t$. The data are monthly and the sample period is 1926 to 2014 for Credit and Term. Standard errors are in parentheses and adjust for heteroskedasticity. All factors are annualized in percent per year by multiplying monthly factors by 12.

| | Univariate Regressions | |
|--------------------|-------------------------|-----------------------|
| | (1) Credit $^\sigma$ | (2) Term $^\sigma$ |
| Credit | 0.44 (0.05) | |
| Term | | 0.18 (0.02) |
| Alpha (α) | 1.48 (0.40) | 1.25 (0.86) |
| N | 1,050 | 1,050 |
| R^2 | 0.20 | 0.03 |
| RMSE | 12.75 | 28.45 |

Table IA. II. Alphas Using Expected Variance. We run time-series regressions of each managed factor on the nonmanaged factor. Here our managed portfolios make use of the full forecasting regression for log variances rather than simply scaling by lagged realized variances. The managed factor scales by the factors' inverse conditional variance. The data are monthly and the sample is 1926 to 2015, except for the factors RMW and CMA, which start in 1963, and the FX carry factor, which starts in 1983. Standard errors are in parentheses and adjust for heteroskedasticity. All factors are annualized in percent per year by multiplying monthly factors by 12.

Table IA. IV. Alphas of Volatility-managed Factors Controlling for Basic Risk Factors. We run time-series regressions of each managed factor on the four Fama-French Carhart factors. The managed factor, f_t^σ , scales by the factors' inverse realized variance in the preceding month, $f_t^\sigma = \frac{c}{RV_{t-1}^2} f_t$. The data are monthly and the sample is 1926 to 2015. Standard errors are in parentheses and adjust for heteroskedasticity. All factors are annualized in percent per year by multiplying monthly factors by 12.

Table IA. V. Alphas of Volatility-managed Factors Controlling for Additional Risk Factors. We run time-series regressions of each managed factor on the 6 Fama-French Carhart factors. The managed factor, f^σ , scales by the factors' inverse realized variance in the preceding month, $f_t^\sigma = \frac{c}{RV_{t-1}^2} f_t$. The data are monthly and the sample is 1963 to 2015. Standard errors are in parentheses and adjust for heteroskedasticity. All factors are annualized in percent per year by multiplying monthly factors by 12.

Figure IA. 1. Increase in Volatility-Managed Sharpe Ratios by Country. The figure plots the change in Sharpe ratio for managed versus nonmanaged portfolios across 20 OECD countries. The change is computed as the Sharpe ratio of the volatility-managed country index minus the Sharpe ratio of the buy-and-hold country index. All indices are from Global Financial Data. For many series, the index only contains daily price data and not dividend data, and thus our results are not intended to accurately capture the level of Sharpe ratios but should still capture their difference well to the extent that most of the fluctuations in monthly volatility are driven by daily price changes. All indices are converted to USD and are taken over the U.S. risk-free rate from Ken French. The average change in Sharpe ratio is 0.15 and the value is positive in 80% of cases.

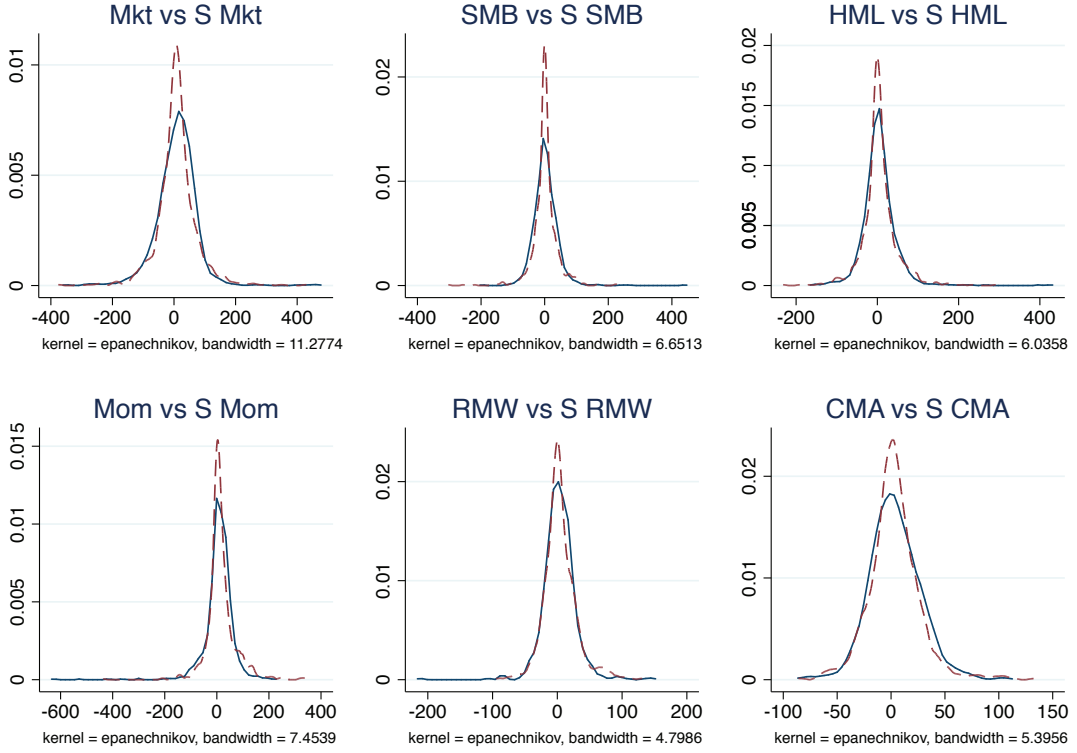

Figure IA. 2. Distribution of Volatility-Managed Factors. The figure plots the full distribution of managed factors (S) versus nonmanaged factors estimated using kernel density estimation. The managed factor, f^σ , scales by the factors' inverse realized variance in the preceding month, $f_t^\sigma = \frac{c}{RV_{t-1}^2} f_t$. In particular, for each panel we plot the distribution of f_t (solid line) along with the distribution of $\frac{c}{RV_{t-1}^2} f_t$ (dashed line).

Figure IA. 3. Rolling Window Alphas. We plot the alpha of our strategy for rolling 30-year windows. We only show results for the market return here for brevity. Each point corresponds to using the 30 years of data up until that time period. We also plot the average experienced volatility for the same window. We see that the alpha of our strategy is highest during subsamples when volatility is relatively high. This is consistent with the strategy being more profitable in times when volatility varies substantially.
